Assessment of Evidence for COVID-19-Related Treatments: Updated 10/28/2020

The information contained in this evidence table is emerging and rapidly evolving because of ongoing research and is subject to the professional judgment and interpretation of the practitioner due to the uniqueness of each medical facility’s approach to the care of patients with COVID-19 and the needs of individual patients. ASHP provides this evidence table to help practitioners better understand current approaches related to treatment and care. ASHP has made reasonable efforts to ensure the accuracy and appropriateness of the information presented. However, any reader of this information is advised ASHP is not responsible for the continued currency of the information, for any errors or omissions, and/or for any consequences arising from the use of the information in the evidence table in any and all practice settings. Any reader of this document is cautioned that ASHP makes no representation, guarantee, or warranty, express or implied, as to the accuracy and appropriateness of the information contained in this evidence table and will bear no responsibility or liability for the results or consequences of its use.

ASHP’s patient medication information is available at http://www.safemedication.com/. Visit our website for the latest information on current drug shortages.

Selected entries were updated 10/28/20; these can be identified by the date that appears in the Drug(s) column. Within updated entries, select revisions that include the most important new information (e.g., new clinical trial data, new or revised guidance) are marked by **.

| **Baloxavir**   | 8:18.92    | Antiviral active against influenza viruses     | Only very limited data available regarding use of baloxavir for treatment of COVID-19          |         | A baloxavir marboxil dosage of 80 mg on day 1 and on day 4, and another dose of 80 mg on day 7 (as needed; not to exceed 3 total doses) was used in one open-label COVID-19 study in adults in China. 5  
**Updated 10/28/20** | No data support use of baloxavir in the treatment of COVID-19  
**** NIH COVID-19 Treatment Guidelines Panel states that treatment of influenza is the same in all pts regardless of SARS-CoV-2 coinfection. 3 (See Neuraminidase Inhibitors in this Evidence Table.)  
** CDC states that baloxavir may be used for the treatment of suspected or confirmed uncomplicated influenza in outpatients; the drug is not recommended for use in pregnant or nursing women, as monotherapy in severely immunosuppressed pts, or for the treatment of severe influenza. 5 |
| Chloroquine Phosphate | 8:30.08 | Antimalarial (4-aminoquinoline derivative) | Only limited clinical trial data available to date to evaluate use of chloroquine for treatment or prevention of COVID-19  
**Updated 10/15/20**  
In vitro activity against SARS-CoV-2 in infected Vero E6 cells reported; some evidence it may block infection in Vero E6 cells exposed to SARS-CoV-2  
Active in vitro against SARS-CoV-1 and MERS-CoV  
Has immunomodulatory activity that theoretically could contribute to an anti-inflammatory response in patients with viral infection  
Small, randomized study in hospitalized adults in China compared chloroquine with LPV/RTV (Huang et al): 10 pts (7 with moderate and 3 with severe COVID-19) received chloroquine (500 mg twice daily for 10 days) and 12 pts (7 with moderate and 5 with severe COVID-19) received LPV/RTV (lopinavir 400 mg/ritonavir 100 mg twice daily for 10 days). All 10 pts treated for treatment of COVID-19  
Optimal dosage and duration of treatment not known 25  
Consider: 500 mg of chloroquine phosphate is equivalent to 300 mg of chloroquine base 17  
Oral chloroquine phosphate dosage suggested in the EUA (now revoked): For treatment of hospitalized adults and adolescents weighing 50 kg or more, suggested dosage was 1 g on day 1, then 500 mg daily for 4-7 days of total treatment based on clinical evaluation. 25  
FDA now states that this dosage regimen is unlikely to have an antiviral effect in pts with COVID-19 based on a reassessment of in vitro EC50/EC90 data and calculated lung concentrations; it is now recommended that patients with severe or critical COVID-19 be treated with lopinavir/ritonavir, in combination with inhaled interferon-α, in the presence of severe COVID-19  
Efficacy and safety of chloroquine for treatment or prevention of COVID-19 not established 10, 24, 39  
No data to date indicating that in vitro activity against SARS-CoV-2 corresponds with clinical efficacy for treatment or prevention of COVID-19  
Data from randomized, controlled clinical trials needed to substantiate initial reports of efficacy of 4-aminoquinoline antimalarials for treatment of COVID-19, guide decisions regarding the most appropriate pts for treatment with such drugs, and identify optimal dose and treatment duration  
Additional data needed regarding toxicity profile when used in patients with COVID-19 |

<td>Hydroxychloroquine</td>
<td></td>
<td>with chloroquine had negative RT-PCR results for SARS-CoV-2 by day 13 and were discharged from the hospital by day 14; 11/12 pts (92%) treated with LPV/RTV were negative for SARS-CoV-2 at day 14 and only 6/12 (50%) were discharged from the hospital by day 14. <strong>Note:</strong> Results suggest that chloroquine was associated with shorter time to RT-PCR conversion and quicker recovery than LPV/RTV; however, this study included a limited number of pts and the median time from onset of symptoms to initiation of treatment was shorter in those treated with chloroquine than in those treated with LPV/RTV (2.5 vs 6.5 days, respectively). Double-blind, randomized, phase 2b study in Brazil (Borba et al; NCT04323527): Efficacy and safety of two different chloroquine dosages were evaluated for adjunctive therapy in hospitalized adults with severe COVID-19. According to the initial study protocol, pts were randomized 1:1 to receive high-dose chloroquine (600 mg twice daily for 10 days) or lower-dose chloroquine (450 mg twice daily on day 1, then 450 mg once daily on days 2-5); all pts also received azithromycin and ceftriaxone and some also received oseltamivir. An unplanned interim analysis was performed and the high-dose arm of the study was halted because of toxicity concerns, particularly QTc prolongation and ventricular tachycardia, and because more deaths were reported in this arm. Analysis of data available for the first 81 enrolled pts indicated that, by day 13, 16/41 pts (39%) treated with the high-dose regimen had died vs 6/40 (15%) treated with the lower-dose regimen. QTc &gt;500 msec occurred more frequently in the high-dose group (18.9%) than in the lower-dose group (11.1%). <strong>Note:</strong> The high-dose arm included more pts prone to cardiac complications than the lower-dose arm. Data at the time of the interim analysis were insufficient to evaluate efficacy. See Hydroxychloroquine in this Evidence Table for additional information on clinical trials and experience with</td>

<td>4-aminoquinoline antimalarials in the management of COVID-19. Several clinical trials to evaluate chloroquine for treatment of COVID-19 are registered at clinicaltrials.gov, including the following: ¹⁰ NCT04328493 NCT04331600 NCT04344951 NCT04345419 NCT04353336 NCT04420247 NCT04428268 Several clinical trials to evaluate chloroquine for prevention of COVID-19 in the healthcare setting are registered at clinicaltrials.gov, including the following: ¹⁰ NCT04303507 NCT04333732 NCT04349371</td>
<td>should be used concomitantly with drugs that pose a moderate to high risk for QT prolongation (e.g., antiarrhythmics, antipsychotics, antifungals, fluoroquinolones, macrolides [including azithromycin]) only if necessary. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving chloroquine (or hydroxychloroquine). ³⁵ FDA issued a safety alert regarding adverse cardiac effects (e.g., prolonged QT interval, ventricular tachycardia, ventricular fibrillation) reported with use of chloroquine or hydroxychloroquine (either alone or in conjunction with azithromycin or other drugs known to prolong QT interval) in hospital and outpatient settings; FDA cautions against use of chloroquine or hydroxychloroquine outside of a clinical trial or hospital setting and urges healthcare professionals and pts to report adverse effects involving these drugs to FDA MedWatch. ³⁵ Emergency use authorization (EUA) for chloroquine (now revoked): Effective June 15, 2020, FDA has revoked the EUA for chloroquine and hydroxychloroquine previously issued on March 28, 2020 that permitted distribution of the drugs from the strategic national stockpile (SNS) for use in adults and adolescents weighing 50 kg or more hospitalized with COVID-19 for whom a clinical trial was not available or participation not feasible. ²⁴, ⁵⁷ Based on a review of new information and reevaluation of information available at the time the EUA was issued, FDA concluded that the original criteria for issuance of the EUA for these drugs are no longer met. ⁵⁷ Based on the totality of scientific evidence available, FDA concluded that it is unlikely that chloroquine and hydroxychloroquine may be effective in treating COVID-19 and, in light of ongoing reports of serious cardiac adverse...</td>

<td>Favipiravir (Avigan®, Avifavir®, Favilavir)</td>
<td>8:18.32 Antiviral</td>
<td>Broad-spectrum antiviral with in vitro activity against various viruses, including coronaviruses 1–5</td>
<td>Limited clinical trial data available to date to evaluate use of favipiravir in the treatment of COVID-19</td>
<td>A favipiravir dosage of 1600 mg twice daily on day 1, then 600 mg twice daily thereafter for 7–10 or 14 days was used in several open-label COVID-19 studies in adults and adolescents ≥16 years of age in other countries 6, 12, 24</td>
<td>Not commercially available in the US Efficacy and safety of favipiravir for treatment of COVID-19 not established Additional data needed to substantiate initial reports of efficacy for treatment of COVID-19 and identify optimal dosage and treatment duration Given the lack of pharmacokinetic and safety data for the high favipiravir dosages proposed for treatment of COVID-19, the drug should be used with caution at such dosages. 19, 20, 21 Favi- piravir is associated with QT prolongation. 21 Some have suggested close cardiac and hepatic monitoring during treatment, as well as monitoring of plasma and tissue concentrations of the drug and, if possible, the active metabolite. 19, 20, 21 Some data suggest that favipiravir exposure may be greater in Asian populations. 17, 19 Early embryonic deaths and teratogenicity observed in animal studies. Favipiravir is contraindicated in women with known or suspected pregnancy and precautions should be taken to avoid pregnancy during treatment with the drug. 14 Based on a pharmacokinetic interaction, if favipiravir is used in pts receiving acetaminophen, the maximum recommended daily dosage of acetaminophen is 3 g. 17, 18 Note that favipiravir-induced fever has been described in 2 COVID-19 pts being treated with the drug. 36</td>

<tr>
<td>favipiravir</td>
<td></td>
<td><strong>Open-label, prospective, randomized, multicenter study</strong> in patients hospitalized with asymptomatic or mild COVID-19 in Japan (jRCTs041190120): Early treatment (beginning on day of hospital admission) with favipiravir (two 1800-mg doses given orally at least 4 hours apart on day 1, then 800 mg orally twice daily for a total of up to 19 doses over 10 days) (n=36) was not associated with significant improvement in viral clearance compared with late treatment with favipiravir (same regimen beginning day 6 after admission) (n=33). Viral clearance occurred by day 6 in 66.7 and 56.1% of patients in the early and late treatment groups, respectively. Viral clearance was assessed by RT-PCR of nasopharyngeal specimens. Most common adverse effect was transient hyperuricemia (84.1% of patients). In a small, open-label, nonrandomized study in patients with non-severe COVID-19 in China (ChiCTR2000029600), favipiravir (1600 mg orally twice daily on day 1, then 600 mg orally twice daily on days 2–14) (n=35) was associated with decreased median time to viral clearance (4 vs 11 days) and higher improvement rate on chest CT imaging on day 14 (91 vs 62%) compared with the control group receiving lopinavir/ritonavir (n=45); both groups also received aerosolized interferon α-1b. In a prospective, observational, single-center study in 174 adults in Turkey with probable or confirmed COVID-19 (20.1% with mild disease, 61.5% with moderate disease, 18.4% with severe pneumonia) admitted to the hospital within a median of 3 days after symptom onset, 32 pts received a regimen that included favipiravir. Most pts who received favipiravir (93.8%) received the drug either in combination with, or as sequential therapy to, hydroxychloroquine with or without azithromycin. In pts who received a favipiravir-containing regimen, the median time to defervescence and to clinical improvement on therapy was 3 and 6 days, respectively. Critically ill pts with sepsis and/or ARDS at the time of admission were excluded.</td>
<td>2400 mg, 2400 mg, and 1200 mg given 8 hours apart on day 1, then a maintenance dosage of 1200 mg every 12 hours on days 2–10. For the treatment of COVID-19, one pharmacokinetic simulation model suggested that a dosage of 2400 mg twice daily on day 1, followed by 1600 mg twice daily on days 2–10 should achieve adequate favipiravir trough plasma concentrations and may be more pharmacologically relevant than lower dosages. Pharmacokinetic data are available from a study in critically ill pts with COVID-19 requiring mechanical ventilation who received a favipiravir dosage of 1600 mg twice daily on day 1, then 600 mg twice daily on days 2–5 (or longer if needed) via NG tube. Trough serum concentrations of the drug in most samples were lower than the lower limit of quantification and lower than the in vitro EC50 of the drug reported for SARS-CoV-2; trough concentrations in these critically ill pts also were much lower than those previously reported in healthy individuals who received the same dosage. While its molecular weight, protein binding rate, and volume of distribution suggest that favipiravir would be eliminated by dialysis, data from a COVID-19 pt treated with favipiravir (1800 mg twice daily on day 1, then 800 mg twice daily) who was undergoing hemodialysis (2 or 3 times weekly) indicated that blood concentrations of the drug were similar to those reported in nondialysis pts. Data from 4 critically ill pts with COVID-19 who received favipiravir 1600 mg twice daily on day 1, then 600 mg twice daily on days 2–7 (a dosage considered to be “low dose”) indicate that the drug was well-tolerated in these pts.</td>

|         |            |           | **In a prospective, single-center study** in 13 pts requiring mechanical ventilation for severe COVID-19 in Japan, pts received favipiravir (3600 mg orally on day 1, then 1600 mg orally on days 2–14), along with methylprednisolone, and low molecular weight heparin (LMWH) or unfractionated heparin. Improvements in PaO₂/FiO₂ (P/F ratio), interleukin-6 concentration, and preparepsin concentration suggested that favipiravir may have some effect on inflammatory mediators, but could not completely control inflammatory mediators or respiratory status.  

**In a retrospective, observational, multicenter study** in 63 adults with COVID-19 in Thailand who received favipiravir (median loading dose of 47.4 mg/kg on day 1 and median maintenance doses of 17.9 mg/kg per day for a median total duration of 12 days), clinical improvement at day 7 was reported in 66.7% of patients (92.5% in patients not requiring oxygen supplementation, 47.2% in patients requiring oxygen supplementation) and clinical improvement at day 14 was reported in 85.7% of patients (100% in patients not requiring oxygen supplementation, 75% in patients requiring oxygen supplementation). Overall mortality at day 28 was 4.8%. Nearly all patients also received a chloroquine-based therapy and an HIV protease inhibitor. Multivariate analysis revealed that older age, higher baseline disease severity, and loading doses <45 mg/kg per day were negative predictors of early clinical improvement.  

**In a retrospective cohort study** of 26 pts with COVID-19 who received various antiviral regimens in Japan, 3 pts ≥74 years of age received treatment that included favipiravir; 2 of these pts demonstrated improvement and 1 pt died.  

**In a case series** of 11 adults admitted to the ICU with COVID-19 at a single center in Japan from 4/6/20 to 4/21/20 who received favipiravir (3600 mg on day 1, then 1600 mg daily thereafter for a median of 14 days) in combination with nafamostat mesylate (not commercially available in the USA). |        |          |

<td>HIV Protease Inhibitors</td>
<td>8:18.08.08 HIV Protease Inhibitors</td>
<td><strong>Updated 10/28/20</strong></td>
<td><strong>Lopinavir (LPV):</strong> Some evidence of in vitro activity against SARS-CoV-2 in Vero E6 cells; evidence of in vitro activity against SARS-CoV-1 and MERS-CoV; some evidence of benefit in animal studies for treatment of MERS-CoV. <strong>Atazanavir (ATV):</strong> Some evidence that ATV alone or in combination with ritonavir (ATV/RTV) has in vitro activity against SARS-CoV-2 in Vero E6 cells, human epithelial pulmonary cells (A549), and human monocytes. <strong>Daranavir (DRV):</strong> In one study, DRV with cobicistat (DRV/c) randomized, open-label trial in China (Cao et al) in hospitalized adults with severe COVID-19 compared LPV/RTV in combination with standard care (99 pts) vs standard care alone (100 pts). Primary end point was time to clinical improvement (time from randomization to improvement of two points on a seven-category ordinal scale or hospital discharge, whichever came first). In ITT population, time to clinical improvement was not shorter with LPV/RTV compared with standard care (median time to clinical improvement 16 days in both groups); in modified ITT population, median time to clinical improvement 15 days in LPV/RTV group and 16 days in standard care only group. The 28-day mortality rate was numerically lower in LPV/RTV group (19.2% vs 25% in ITT population; 16.7% vs 25% in modified ITT population). Some evidence that LPV/RTV initiation within 12 days after symptom onset is associated with shorter time to clinical improvement. No significant differences in reduction of viral RNA load, duration of viral RNA detectability, duration of oxygen therapy, duration of hospitalization, or time from randomization to death. LPV/RTV stopped early in 13 pts because of adverse effects. <strong>Nelfinavir (NFV),</strong> Ri-tonavir (RTV), Saquinavir (SQV), and Tipranavir (TPV): Some evidence of in vitro activity against SARS-CoV-2 in Vero E6 cells. <strong>LPV/RTV:</strong> Some evidence of clinical benefit when used in conjunction with ribavirin and/or interferon in pts with SARS or MERS. <strong>LPV/RTV vs chloroquine in small, randomized study in hospitalized adults with COVID-19 in China (Huang et al):</strong> 10 pts (7 with moderate and 3 with severe disease) received chloroquine (500 mg twice daily for 10 days) and 12 pts (7 with moderate and 5 with severe disease) received LPV/RTV (lopinavir 400 mg/ritonavir 100 mg twice daily for 10 days). All 10 pts treated with chloroquine had negative RT-PCR results for SARS-CoV-2 by day 13 and were discharged from the hospital by day 14; 10 pts (7 with moderate and 3 with severe disease) received LPV/RTV (lopinavir 400 mg/ritonavir 100 mg twice daily for 10 days) and 12 pts (7 with moderate and 5 with severe disease) received LPV/RTV (lopinavir 400 mg/ritonavir 100 mg twice daily for 10 days). All 10 pts treated with LPV/RTV had negative RT-PCR results for SARS-CoV-2 by day 13 and were discharged from the hospital by day 14. <strong>LPV/RTV (COVID-19):</strong> LPV 400 mg/RTV 100 mg orally twice daily for 10-14 days 3, 10, 24 <strong>LPV/RTV (COVID-19):</strong> LPV 400 mg/RTV 100 mg orally twice daily with or without umifenovir (Arbidol® 200 mg every 8 hours) 5 <strong>LPV/RTV (COVID-19):</strong> LPV 400 mg/RTV 100 mg orally twice daily for no longer than 10 days 3 with or without interferon (5 million units of interferon-α or equivalent twice daily given in 2 mL of sterile water by nebulization) and with or without ribavirin for up to 10 days 5, 13 <strong>LPV/RTV (SARS):</strong> LPV 400 mg/RTV 100 mg orally twice daily for 14 days with ribavirin (4-g oral loading dose, then 1.2 g orally every 8 hours or 8 mg/kg IV every 8 hours) 1 <strong>LPV/RTV (MERS):</strong> LPV 400 mg/RTV 100 mg orally twice daily with ribavirin (various regimens) and/or interferon-α; LPV 400 mg/RTV 100 mg orally twice daily with interferon β-1b (0.25 mg/mL sub- Q on alternate days) for 14 days 1, 4, 8 <strong>LPV/RTV:</strong> Efficacy for the treatment of COVID-19, with or without other antivirals, not established 22, 23 <strong>Darunavir:</strong> Manufacturer states they have no clinical or pharmacologic evidence to support use of DRV/c for treatment of COVID-19. Results of an open-label, controlled study in China indicated that a 5-day regimen of DRV/c was not effective for treatment of COVID-19 21, 26 and there are no published clinical studies that have evaluated efficacy and safety of DRV/RTV or the fixed combination of DRV, cobicistat, emtricitabine, and tenofovir alafenamide for treatment of COVID-19. 21 <strong>Atazanavir, Nelfinavir, Saquinavir, Tipranavir:</strong> No clinical trial data to date to support use in the treatment of COVID-19 22 **NIH COVID-19 Treatment Guidelines Panel recommends against the use of LPV/RTV or other HIV protease inhibitors for the treatment of COVID-19, except in a clinical trial. The panel states that, based on the pharmacodynamics of LPV/RTV, there are concerns whether drug concentrations achieved with oral doses of the drug are adequate to inhibit SARS-CoV-2 protease. In addition, clinical trials to date using LPV/RTV have not demonstrated a clinical benefit in patients with COVID-19. 22 <strong>IDSA recommends that LPV/RTV be used for the treatment of COVID-19 only in the context of a clinical trial</strong> 23</td>

<td><strong>LPV/RTV with ribavirin and interferon β-1b vs LPV/RTV alone in open-label, randomized trial in adults with mild to moderate COVID-19 in Hong Kong (Hung et al; NCT04276688):</strong> 127 pts were randomized 2:1 to receive LPV/RTV (LPV 400 mg/RTV 100 mg) twice daily for 14 days) with ribavirin (400 mg twice daily) and interferon β-1b (8 million IU sub-Q on alternate days for up to 3 doses depending on how soon treatment initiated after symptom onset) or a 14-day regimen of LPV/RTV alone. Median time to negative RT-PCR results for SARS-CoV-2 in nasopharyngeal samples was 7 days in pts treated with the 3-drug regimen vs 12 days in those treated with LPV/RTV alone; median duration of hospitalization was 9 or 14.5 days, respectively. Adverse effects reported in 48% of those treated with the 3-drug regimen and in 49% of those treated with LPV/RTV alone. <strong>Note:</strong> Results indicate a 3-drug regimen that included LPV/RTV, ribavirin, and interferon β-1b was more effective than LPV/RTV alone in pts with mild to moderate COVID-19, especially when treatment was initiated within 7 days of symptom onset. 25</td>

<td></td>
<td>LPV/RTV in randomized, controlled, open-label, platform trial (NCT04381936; RECOVERY): This study is enrolling pts with suspected or confirmed COVID-19 from 176 hospitals in the UK. In the LPV/RTV arm (now terminated), 1616 pts were randomized to receive LPV/RTV (LPV 400 mg/RTV 100 mg every 12 hours for 10 days or until discharge, whichever came first) plus standard of care and 3424 pts were randomized to standard of care alone. At the time of study enrollment, 26% of pts did not require oxygen support, 70% required oxygen support, and only 4% were on mechanical ventilation. The primary outcome was all-cause mortality at day 28. Results of this study indicated that LPV/RTV is not an effective treatment for COVID-19 in hospitalized pts. Mortality rate at 28 days was 23% in those treated with LPV/RTV plus standard of care vs 22% in those treated with standard of care alone. In addition, LPV/RTV did not reduce the time to hospital discharge (median length of stay was 11 days in both groups) and, in those not requiring mechanical ventilation at baseline, LPV/RTV did not decrease the risk of progression to mechanical ventilation (10% in the LPV/RTV group vs 9% in standard of care alone group). Results were consistent across all prespecified pt subgroups (age, sex, ethnicity, level of respiratory support, time since symptom onset, and predicted 28-day mortality risk at time of randomization). 27</td>

hospitalization. **Interim results (not peer reviewed) have been announced, including results for the LPV/RTV treatment arm that was discontinued.** From March 22 to July 4, 2020, 1411 pts were randomized to receive LPV/RTV (two tablets containing LPV 200 mg/RTV 50 mg orally twice daily for 14 days) and 1380 pts were randomized to LPV/RTV control (i.e., standard of care). Preliminary data analysis for the intention-to-treat (ITT) population indicated that LPV/RTV did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for LPV/RTV in the ITT population was 1.00; 148/1399 pts treated with LPV/RTV (9.7%) and 146/1372 pts treated with standard of care (10.3%) died. 29

**Daranavir and cobicistat (DRV/c) randomized, open-label trial in China (Chen et al; NCT04252274):** A total of 30 adults with mild, laboratory-confirmed COVID-19 were randomized 1:1 to receive DRV/c (fixed combination darunavir 800 mg/cobicistat 150 mg once daily for 5 days) or no DRV/c (control group); all pts received interferon alfa-2b and standard of care. The primary end point was viral clearance rate at day 7 (defined as RT-PCR negative for SARS-CoV-2 in at least 2 consecutive oropharyngeal swabs collected at least 1-2 days apart). At day 7, viral clearance rate in the intention-to-treat (ITT) population was 47% in those treated with DRV/c and 60% in the control group. In the per-protocol (PP) population, viral clearance rate at day 7 was 50% in those treated with DRV/c and 60% in the control group. The median time from randomization to negative RT-PCR result was 8 and 7 days, respectively. **This study indicated that a 5-day regimen of DRV/c in pts with mild COVID-19 did not provide clinical benefits compared with use of standard care alone.** 26

<tr>
<td>hydroxychloroquine randomized, parallel-group study in adults in China [ChiCTR2000029559]: 31 pts with COVID-19 and pneumonia received hydroxychloroquine sulfate (200 mg twice daily for 5 days) and standard treatment (O₂, antiviral agents, antibacterial agents, immunoglobulin, with or without corticosteroids) and 31 other pts received standard treatment alone (control group). Exclusion criteria included severe and critical illness. Pts assessed at baseline and 5 days after treatment initiation for time to clinical recovery (TTCR; defined as normalization of fever and cough relief maintained for &gt;72 hours), clinical characteristics, and changes on chest CT. It was concluded that hydroxychloroquine was associated with symptom relief since time to fever normalization was shorter in hydroxychloroquine group (2.2 days) vs control group (3.2 days), time to cough remission was shorter in hydroxychloroquine group, and pneumonia improved in 25/31 pts (80.6%) in hydroxychloroquine group vs 17/31 pts (54.8%) in control group. Total of 4 pts progressed to severe illness (all in the control group). 31 Note: This study did not include pts with severe disease and pts received other anti-infectives in addition to hydroxychloroquine. At study entry, 9 pts without fever and 9 pts without cough were included in hydroxychloroquine group and 14 pts without fever and 16 pts without cough were included in control group; unclear how these pts were addressed in TTCR calculations. Although initial registered study protocol specified 2 different hydroxychloroquine treatment groups and a placebo group (each with 100 pts) and primary end points of time to negative nucleic acid and T-cell recovery, data provided only for certain clinical symptoms in 62 pts without severe disease and PCR results not reported. 31</td>
<td>Hydroxychloroquine randomized, parallel-group, open-label study in hospitalized adults with mild to moderate COVID-19 in China [ChiCTR2000029868]: 150 pts (148 with mild to moderate disease and 2 with severe disease) were randomized 1:1 to NIH COVID-19 Treatment Guidelines Panel recommends against use of hydroxychloroquine (with or without azithromycin) for the treatment of COVID-19 in hospitalized pts and recommends against use of hydroxychloroquine (with or without azithromycin) for the treatment of COVID-19 in nonhospitalized pts, except in a clinical trial. 35</td>
<td>IDSA recommends against use of hydroxychloroquine for the treatment of COVID-19 in hospitalized pts and also recommends against use of a combined regimen of hydroxychloroquine and azithromycin for the treatment of COVID-19 in hospitalized pts. 38</td>
<td>NIH COVID-19 Treatment Guidelines Panel recommends against the use of any agents, including hydroxychloroquine, for preexposure prophylaxis (PrEP) or postexposure prophylaxis (PEP) for prevention of SARS-CoV-2 infection, except in a clinical trial. 35 The panel states that, to date, no agent is known to be effective for preventing SARS-CoV-2 infection when given before or after an exposure. 35 Because 4-aminoquinolines (hydroxychloroquine, chloroquine) and azithromycin are independently associated with QT prolongation and because concomitant use of the drugs may further increase the risk of QT prolongation, caution is advised if considering use of hydroxychloroquine (with or without azithromycin) in pts with COVID-19, especially in outpatients who may not receive close monitoring and in those at risk for QT prolongation or receiving other drugs associated with arrhythmias. 35, 36, 38, 39, 41-44 NIH panel states that 4-aminoquinolines (hydroxychloroquine, chloroquine) should be used concomitantly with drugs that pose a moderate to high risk for QT prolongation (e.g., antiarrhythmics, antipsychotics, antifungals, fluoroquinolones, macrolides [including azithromycin]) only if necessary.</td>

| receive hydroxychloroquine (1200 mg daily for 3 days, then 800 mg daily for total treatment duration of 2-3 weeks) with standard of care or standard of care alone. Mean time from onset of symptoms to randomization was 16.6 days (range: 3-41 days). Standard of care included IV fluids, O2, various antivirals (e.g., umifenovir, LPV/RTV), antibiotics, and/or glucocorticoid therapy. By day 28, 73% of pts (53 treated with hydroxychloroquine with standard of care and 56 treated with standard of care alone) had converted to negative for SARS-CoV-2. The probability of negative conversion by day 28 in those treated with hydroxychloroquine was similar to that in those treated with standard of care alone; the median time to negative seroconversion (6 and 7 days) also was similar in both groups. Adverse effects reported in 30% of those treated with hydroxychloroquine and 9% of those treated with standard of care alone. Note: Results indicate that use of hydroxychloroquine in pts with mild to moderate COVID-19 did not provide additional benefits compared with use of standard of care alone. 49  

Hydroxychloroquine with azithromycin open-label, nonrandomized study in France (Gautret et al): Preliminary data from an ongoing study in hospitalized pts with confirmed COVID-19 was used to assess efficacy of hydroxychloroquine used alone or with azithromycin; untreated pts were used as a negative control. The primary end point was negative PCR results in nasopharyngeal samples at day 6. Data from 14 pts treated with hydroxychloroquine sulfate (200 mg 3 times daily for 10 days), 6 pts treated with hydroxychloroquine and azithromycin (500 mg on day 1, then 250 mg daily on days 2-5), and 16 pts in the control group were analyzed. At day 6, 8/14 (57%) in the hydroxychloroquine group, 6/6 (100%) in the hydroxychloroquine and azithromycin group, and 2/16 (12.5%) in the control group had negative PCR results. At day 8, a positive PCR was reported in a pt treated with both drugs who had tested negative at day 6. 27 Note: This was a small nonrandomized study that... | | | | In addition, because of the long half-lives of both hydroxychloroquine (up to 40 days) and azithromycin (up to 72 hours), caution is warranted even when these drugs are used sequentially. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving hydroxychloroquine (or chloroquine). 35  

The benefits and risks of hydroxychloroquine (with or without azithromycin) should be carefully assessed; diagnostic testing and monitoring are recommended to minimize risk of adverse effects, including drug-induced cardiac effects. 35, 36, 38, 39, 41-44  

FDA issued a safety alert regarding adverse cardiac effects (e.g., prolonged QT interval, ventricular tachycardia, ventricular fibrillation) reported with use of chloroquine or hydroxychloroquine (either alone or in conjunction with azithromycin or other drugs known to prolong QT interval) in hospital and outpatient settings; FDA cautions against use of chloroquine or hydroxychloroquine for treatment or prevention of COVID-19 outside of a clinical trial or hospital setting and urges healthcare professionals and pts to report adverse effects involving these drugs to FDA MedWatch. 39  

Emergency use authorization (EUA) for hydroxychloroquine (now revoked): Effective June 15, 2020, FDA has revoked the EUA for hydroxychloroquine and chloroquine previously issued on March 28, 2020 that permitted distribution of the drugs from the strategic national stockpile (SNS) for use in adults and adolescents weighing 50 kg or more hospitalized with COVID-19 for whom a clinical trial was not available or participation not feasible. 24, 57 Based on a review of new information and reevaluation of information available at the time the EUA was issued, FDA concluded that the original criteria for issuance... | | |

<td>Hydroxychloroquine with azithromycin</td>
<td></td>
<td></td>
<td>didn’t appear to be designed to compare hydroxychloroquine vs hydroxychloroquine and azithromycin (pts received antibiotics to prevent bacterial superinfection based on clinical judgment). Data on disease severity were unclear (some asymptomatic pts were included when study initiated) and information on disease progression and clinical outcomes was not presented. Hydroxychloroquine with azithromycin open-label, uncontrolled study in France (Molina et al): 11 adults hospitalized with COVID-19 received hydroxychloroquine (600 mg daily for 10 days) and azithromycin (500 mg on day 1, then 250 mg daily on days 2-5). At time of treatment initiation, 8/11 pts had significant comorbidities associated with poor outcomes and 10/11 had fever and received O2. Within 5 days, 1 pt died and 2 transferred to ICU; the regimen was discontinued in 1 pt after 4 days because of prolonged QT interval. Nasopharyngeal samples were still PCR positive at days 5 and 6 in 8/10 pts tested. Note: In this small uncontrolled study, hydroxychloroquine and azithromycin regimen did not result in rapid viral clearance or provide clinical benefit. Hydroxychloroquine with azithromycin uncontrolled, retrospective, observational study in France (Gautret et al): 80 adults with confirmed COVID-19 (including 6 pts included in a previous study by the same group) were treated with hydroxychloroquine sulfate (200 mg 3 times daily for 10 days) and azithromycin (500 mg on day 1, then 250 mg daily on days 2-5). Majority (92%) were considered low risk for clinical deterioration (low national early warning score for COVID-19 based on age, respiratory rate, O2 saturation, temperature, BP, pulse, level of consciousness); only 15% had fever; 4 pts were asymptomatic carriers; mean time from onset of symptoms to treatment initiation was 4.9 days. Clinical outcome, contagiousness as assessed by nasopharyngeal PCR assay and culture, and length of stay in infectious disease (ID) unit were evaluated in pts who were treated for at least 3 days and followed for at least 6 days of the EUA for these drugs are no longer met. Based on the totality of scientific evidence available, FDA concluded that it is unlikely that hydroxychloroquine and chloroquine may be effective in treating COVID-19 and, in light of ongoing reports of serious cardiac adverse events and several newly reported cases of methemoglobinemia in COVID-19 patients, the known and potential benefits of hydroxychloroquine and chloroquine do not outweigh the known and potential risks associated with the use authorized by the EUA. The basis for the FDA decision to revoke the EUA for hydroxychloroquine and chloroquine is summarized below: 1) Suggested hydroxychloroquine and chloroquine dosage regimens as detailed in the EUA fact sheets for healthcare providers are unlikely to produce an antiviral effect. 2) Earlier observations of decreased viral shedding with hydroxychloroquine or chloroquine treatment have not been consistently replicated and recent data from a randomized controlled trial assessing probability of negative conversion showed no difference between hydroxychloroquine and standard of care alone. 3) Current US treatment guidelines do not recommend the use of chloroquine or hydroxychloroquine in hospitalized patients with COVID-19 outside of a clinical trial and the NIH guidelines now recommend against such use outside of a clinical trial. 4) Recent data from a large, randomized, controlled trial showed no evidence of benefit in mortality or other outcomes such as hospital length of stay or need for mechanical ventilation for hydroxychloroquine treatment in hospitalized patients with COVID-19.</td>

|         |            |           | days. Favorable outcome was reported for 81.3%; 15% required O\(_2\); 3 pts transferred to ICU; 1 pt died; mean time to discharge from ID unit was 4.1 days. At day 8, PCR results were negative in 93% of those tested; at day 5, viral cultures were negative in 97.5% of those tested. \(^34\) **Note:** Almost all pts were considered low risk for clinical deterioration (including 4 pts described as asymptomatic carriers) and it is unclear how many would have had spontaneous conversion to negative nasopharyngeal samples during same time frame. Although 80 pts were enrolled, PCR results available for fewer pts beginning on day 3 and only 60 pts represented in day 6 data. This was an uncontrolled study and data presented cannot be used to determine whether a regimen of hydroxychloroquine with azithromycin provides benefits in terms of disease progression or decreased infectiousness, especially for pts with more severe disease.  
**Hydroxychloroquine with azithromycin uncontrolled, observational, retrospective analysis in France (Million et al):** Data for 1061 pts with PCR-documented SARS-CoV-2 RNA who were treated with a regimen of hydroxychloroquine sulfate (200 mg 3 times daily for 10 days) and azithromycin (500 mg on day 1, then 250 mg daily on days 2-5) were analyzed for clinical outcomes and persistence of viral shedding.  
Pts were included in the analysis if they received the combined regimen for at least 3 days and were clinically assessable at day 9. There were 56 asymptomatic and 1005 symptomatic pts; the majority (95%) had relatively mild disease and were considered low risk for clinical deterioration; median age was 43.6 years (range: 14-95 years) and mean time between onset of symptoms and initiation of treatment was 6.4 days. Within 10 days of treatment, good clinical outcome reported in 973 pts (91.7%) and poor clinical outcome reported in 46 pts (4.3%). Persistent nasal carriage of SARS-CoV-2 reported at completion of treatment in 47 pts (4.4%); 8 pts died.\(^37\) | | Consult the FDA letter regarding the revocation of the EUA for hydroxychloroquine and chloroquine and the FDA memorandum explaining the basis for the revocation for additional information. \(^37\) |

<td>Hydroxychloroquine (with or without azithromycin) in a retrospective analysis of patients hospitalized with COVID-19 in US Veterans Health Administration medical centers (Magagnoli et al): Data for 368 males (median age &gt;65 years) treated with hydroxychloroquine in addition to standard supportive management were analyzed for death rate and need for mechanical ventilation. Death rate was 27.8% (27/97) in those treated with hydroxychloroquine, 22.1% (25/113) in those treated with hydroxychloroquine and azithromycin, and 11.4% (18/158) in those not treated with hydroxychloroquine; rate of ventilation was 13.3, 6.9, and 14.1%, respectively. Use of hydroxychloroquine alone (but not use of hydroxychloroquine and azithromycin) was associated with increased overall mortality compared with no hydroxychloroquine; use of hydroxychloroquine with or without azithromycin did not reduce the risk of mechanical ventilation. Note: The pt population included only elderly males 59-75 years of age, many with significant comorbidities. This analysis did not look at efficacy measures.</td>
<td></td>

Two different retrospective studies analyzed outcome data for hospitalized pts with confirmed COVID-19 in New York to assess the effects of treatment with hydroxychloroquine with or without azithromycin (Rosenberg et al, Geleris et al): Results of these studies suggest that use of hydroxychloroquine with or without azithromycin is not associated with decreased in-hospital mortality. 45, 46 |

Rosenberg et al analyzed data for 1438 hospitalized pts (735 received hydroxychloroquine with azithromycin, 271 received hydroxychloroquine alone, 211 received azithromycin alone, 221 received neither drug) and assessed in-hospital mortality (primary outcome). Overall, in-hospital mortality was 20.3%; in-hospital mortality was 25.7, 19.9, 10, or 12.7% in those treated with hydroxychloroquine with azithromycin, hydroxychloroquine alone, azithromycin alone, or neither drug, respectively. 45 |
Geleris et al analyzed data for 1376 hospitalized pts (811 received hydroxychloroquine [486 of these also received azithromycin] and 565 did not receive hydroxychloroquine [127 of these received azithromycin]) and assessed the primary end point of time from study baseline to intubation or death. Overall, 346 pts (25.1%) progressed to a primary end point of intubation and/or death and the composite end point of intubation or death was not affected by hydroxychloroquine treatment (intubation or death reported in 32.3% of pts treated with hydroxychloroquine and 14.9% of pts not treated with the drug). 68

** Large, randomized, controlled, open-label, platform trial evaluating efficacy of various treatments in hospitalized pts with COVID-19 (NCT04381936; RECOVERY): This study is enrolling pts with suspected or confirmed COVID-19 from 176 hospitals in the UK. The protocol-specified primary outcome is all-cause mortality at day 28; secondary outcomes include duration of hospitalization and composite of initiation of invasive mechanical ventilation (including ECMO) or death among those not receiving invasive mechanical ventilation at time of randomization. In the hydroxychloroquine sulfate arm (now terminated), 1561 adults were randomized to receive hydroxychloroquine sulfate (two 800-mg doses given 6 hours apart followed by two 400-mg doses given 12 and 24 hours after the initial dose on day 1, then 400 mg every 12 hours thereafter for 9 days or until hospital discharge, whichever came first) plus standard of care and 3155 were randomized to standard of care alone. Data analyses for this intention-to-treat (ITT) population indicated that hydroxychloroquine did not reduce mortality and did not provide other benefits in pts hospitalized with COVID-19. The 28-day mortality rate was 27% in those treated with hydroxychloroquine plus standard care vs 25% in those treated with standard care alone (death rate ratio 1.09); results were consistent across all subgroups defined at the time of randomization (age,

** Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. Interim results (not peer reviewed) have been announced, including results for the hydroxychloroquine treatment arm that was terminated. From March 22 to June 18, 2020, 954 pts were randomized to receive hydroxychloroquine sulfate (two 800-mg doses given 6 hours apart followed by a 400-mg dose given 12 hours after the initial dose on day 1, then 400 mg twice daily for 10 days) and 909 pts were randomized to hydroxychloroquine control (i.e., standard of care). Preliminary data analysis for the intention-to-treat (ITT) population indicated that hydroxychloroquine did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for hydroxychloroquine in the ITT population was 1.19; 104/947 pts treated with hydroxychloroquine (10.2%) and 84/906 pts treated with standard of care (8.9%) died. \(^{64}\) |            |          |
Retrospective, comparative cohort study evaluating clinical outcomes in hospitalized COVID-19 pts treated with hydroxychloroquine vs hydroxychloroquine with azithromycin vs azithromycin alone (Arshad et al): Data for 2541 consecutive pts with laboratory-confirmed COVID-19 who were admitted to hospitals within the Henry Ford Health System in Michigan and received hydroxychloroquine and/or azithromycin or did not receive these drugs were analyzed. Median age of patients was 64 years; the majority had BMI of 30 or greater and many had various other comorbidities; 68% received corticosteroid treatment and 4.5% received tocilizumab; mSOFA scores were not available for 25% of pts and data were not available regarding duration of symptoms prior to hospitalization; and the median length of hospitalization was 6 days. The primary end point was inpatient mortality; median follow-up was 28.5 days. Results indicated that crude mortality rates were 18.1% in the entire group, 13.5% in the hydroxychloroquine group, 20.1% in the hydroxychloroquine with azithromycin group, 22.4% in the azithromycin group, and 26.4% in those not treated with hydroxychloroquine and/or azithromycin. The primary causes of mortality were respiratory failure (88%), cardiac arrest (4%), and cardiopulmonary arrest and multi-organ failure (8%). Note: Only selected pts with minimal cardiac risk factors received hydroxychloroquine with azithromycin and all pts treated with hydroxychloroquine were monitored closely with telemetry and serial QTc evaluations.

Open-label, randomized study in hospitalized pts with mild to moderate COVID-19 (Cavalcanti et al; Brazil; NCT04322123): Adults hospitalized with COVID-19 were randomized 1:1:1 to receive standard care (control group), hydroxychloroquine (400 mg twice daily for 7 days) with standard care, or hydroxychloroquine (same dosage) plus azithromycin (500 mg once daily for 7 days) with standard care. Pts not requiring supplemental oxygen or only requiring supplemental oxygen at a rate of 4 L/min or less at baseline were enrolled; pts with a

<td></td>
<td>history of severe ventricular tachycardia or with QTc of ≥480 msec or greater at baseline were excluded. The median time from onset of symptoms to randomization was 7 days. The primary outcome was clinical status at day 15 evaluated using a 7-point ordinal scale. Data for the 504 pts in the modified intention-to-treat population with laboratory-confirmed COVID-19 (173 pts in the control group, 159 pts in the hydroxychloroquine group, 172 pts in the hydroxychloroquine and azithromycin group) indicated there was no significant difference in clinical status at day 15 in those treated with hydroxychloroquine with or without azithromycin compared with the control group. There also were no significant differences in secondary outcomes (e.g., need for mechanical ventilation, duration of hospitalization, in-hospital death) among the groups.</td>

Open-label, randomized study in outpatients with mild COVID-19 (Mitja et al; Spain): Total of 293 adults with laboratory-confirmed COVID-19 who did not require hospitalization and had mild symptoms (i.e., fever, acute cough, shortness of breath, sudden olfactory or gustatory loss, influenza-like illness) for less than 5 days before study enrollment were randomized 1:1 to receive hydroxychloroquine (800 mg on day 1, then 400 mg once daily for 6 days) or usual care only. The primary outcome was reduction of viral RNA load in nasopharyngeal swabs at days 3 and 7 after treatment initiation. Median age of pts was 41.6 years, 53% reported chronic health conditions, and 87% were healthcare workers. The median time from symptom onset to randomization was 3 days, and the mean viral load at baseline was 7.9 log_{10} copies/mL. Results indicated that a 7-day hydroxychloroquine regimen did not provide any clinical benefits compared with usual care alone in these outpatients with mild COVID-19. There was no significant reduction in viral load at day 3 or 7 in those treated with hydroxychloroquine vs those treated with usual care only and there was no decrease in median time to resolution of COVID-19 symptoms (10 and 12 days, |

</thead>
</table>

respectively) and no decrease in risk of hospitalization (7 and 6%, respectively).  

**Double-blind, randomized, placebo-controlled study in outpatients with confirmed or probable early COVID-19** (Skipper et al; US and Canada; NCT04308668): A total of 423 symptomatic adults with laboratory-confirmed COVID-19 or with symptoms compatible with COVID-19 and a high-risk exposure to a contact with laboratory-confirmed COVID-19 were randomized 1:1 to receive hydroxychloroquine (initial dose of 800 mg, 600 mg given 6-8 hours later, then 600 mg once daily for the next 4 days) or placebo. Enrolled pts had been symptomatic for no more than 4 days and did not require hospitalization at the time of enrollment. The primary efficacy end point specified in the initial study protocol was subsequently changed to overall symptom severity over 14 days; symptoms and severity were self-reported by the pts at days 3, 5, 10, and 14 using a survey with a 10-point visual analog scale. Median age of pts was 40 years, 68% reported no chronic medical conditions, 57% were healthcare workers, 25% had been exposed to COVID-19 through household contacts, and 56% of pts had enrolled within 1 day of symptom onset. **Results indicated that a 5-day hydroxychloroquine regimen did not provide any substantial improvement in symptom severity in these outpatients with confirmed or probable COVID-19.** At day 5, 54% of pts in the hydroxychloroquine group and 56% in the placebo group reported symptoms. At day 14, 24% of those treated with hydroxychloroquine had ongoing symptoms compared with 30% of those treated with placebo. Overall, the decrease in prevalence of symptoms and the reduction in symptom severity score over 14 days were not significantly different between the two groups (symptom severity in the 10-point scale decreased 2.6 points in those treated with hydroxychloroquine and 2.3 points in those treated with placebo). In addition, there was no difference between the groups in the incidence of hospitalization or death.

Updated 10-28-20. The current version of this document can be found on the [ASHP COVID-19 Resource Center](https://www.ashp.org). This work is licensed under a [Creative Commons Attribution-NonCommercial 4.0 International License](https://creativecommons.org/licenses/by-nc/4.0/).
Large, multinational, retrospective study analyzed outcome data for hospitalized pts with confirmed COVID-19 to assess the effects of hydroxychloroquine or chloroquine used with or without a macrolide (Mehra et al; now retracted): Original publication included data obtained worldwide for 96,032 pts hospitalized with COVID-19 between Dec 20, 2019 and Apr 14, 2020, including 14,888 pts who received chloroquine or hydroxychloroquine with or without a macrolide (azithromycin or clarithromycin) initiated within 48 hours of diagnosis (treatment group) and 81,144 pts who did not receive these drugs (control group). Based on those data, in-hospital mortality rate in the control group was 9.3% compared with 18% in those treated with hydroxychloroquine alone (n=3016), 23.8% in those treated with hydroxychloroquine and a macrolide (n=6221), 16.4% in those treated with chloroquine alone (n=1868), and 22.2% in those treated with chloroquine and a macrolide (n=3783). Note: This published study has now been retracted by the publisher at the request of 3 of the original authors. Concerns were raised with respect to the veracity of the data and analyses conducted by a global healthcare data collaborative. Hydroxychloroquine for postexposure prophylaxis of COVID-19 randomized, placebo-controlled trial in the US and Canada (NCT04308668): Asymptomatic adults with occupational or household exposure to an individual with COVID-19 were randomly assigned 1:1 to receive postexposure prophylaxis with a 5-day regimen of hydroxychloroquine sulfate (initial 800-mg dose followed by a 600-mg dose given 6–8 hours after first dose on day 1, then 600 mg once daily for 4 additional days) or placebo (folate tablets). A total of 821 asymptomatic adults were enrolled within 4 days after COVID-19 exposure (414 randomized to hydroxychloroquine and 407 randomized to placebo); 66% were healthcare workers. Overall, 88% of participants reported high-risk exposures (occurred at a distance of <6 feet for >10 minutes while...
not wearing a face mask or eye shield) and the others reported moderate-risk exposures (occurred at a distance of <6 feet for >10 minutes while wearing a face mask but no eye shield). Note: Participants were recruited primarily through social media outreach and traditional media platforms and were enrolled using an internet-based survey. The exposure event and subsequent onset of new symptoms and illness compatible with COVID-19 after enrollment were self-reported using email surveys on days 1, 5, 10, and 14 and at 4-6 weeks. Results of these surveys and information obtained using additional forms of follow-up indicated that confirmed or probable COVID-19 (based on self-reported symptoms or PCR testing) developed in 13% of participants overall (107/821) and did not differ significantly between those who received hydroxychloroquine prophylaxis (11.8%) and those who received placebo (14.3%).

Note: The various limitations of the trial design should be considered when interpreting the results. Exposure to someone with confirmed COVID-19, time from the exposure event to initiation of prophylaxis, and all outcome data (including possible COVID-19 symptoms and PCR test results) were self-reported by study participants. COVID-19 was confirmed with PCR testing in only a small percentage (<3%) of participants who self-reported COVID-19 symptoms. Survey results indicated that full adherence to the 5-day prophylaxis regimen was reported by only 75% of patients randomized to hydroxychloroquine and 83% of those randomized to placebo. In addition, a total of 52 participants did not complete any surveys after study enrollment.

Double-blind, placebo-controlled, randomized trial in the US to evaluate hydroxychloroquine for preexposure prophylaxis of COVID-19 (Abella et al; NCT04329923): Healthcare personnel working ≥20 hours per week in hospital-based units (nurses, physicians, certified nursing assistants, emergency technicians, respiratory therapists) who had no known history of SARS-CoV-2 infection and no
symptoms suggestive of COVID-19 within 2 weeks prior to trial enrollment were randomized 1:1 to receive hydroxychloroquine (600 mg daily) or placebo for preexposure prophylaxis of COVID-19. Nasopharyngeal swab tests for SARS-CoV-2 and serologic tests for anti-nucleocapside IgG, anti-spike protein receptor-binding domain (RBD) IgM, and anti-RBD IgG were performed at the time of randomization (baseline) and at 4 and 8 weeks; participants also were surveyed weekly for adherence and adverse events. The primary outcome was rate of conversion to SARS-CoV-2-positive status based on nasopharyngeal swab testing at 8 weeks. A total of 125 participants were evaluable for the primary outcome (64 in the hydroxychloroquine arm and 61 in the placebo arm); 22 of the evaluable participants (17.6%) discontinued study treatment early. Results indicate that preexposure prophylaxis with hydroxychloroquine did not provide clinical benefits in hospital-based healthcare personnel. The rate of COVID-19 positivity was similar in the hydroxychloroquine group (6.3%) and placebo group (6.6%); cases of infection occurred throughout the 8-week study period. All 8 individuals who became infected (4 in each group) were either asymptomatic or had mild disease with full recovery; none required hospitalization. After reviewing data at the time of a second planned interim analysis, the data safety and monitoring board recommended that the trial be terminated early. Grade 3 or 4 adverse events were not reported in any participants; the incidence of adverse events was significantly higher in the hydroxychloroquine group than the placebo group (45 vs 26%). **Note:** Limitations of this trial include the possibility that it was insufficiently powered because of low enrollment, data are not available to quantify the frequency of participant exposures to the virus or specific timing of such exposures, and most participants were young and healthy.62

Retrospective cohort study in the US to evaluate possible SARS-CoV-2 preventive benefits of hydroxychloroquine therapy used in pts with rheumatic conditions

<tr>
<td>(Gentry et al): Possible benefit of long-term hydroxychloroquine therapy used for management of rheumatic conditions for prevention of SARS-CoV-2 infection in such pts was investigated retrospectively using data obtained from the US Veterans Affairs Medical Centers (VAMCs) database. Adults in the database with ICD-10 diagnostic code entries for rheumatoid arthritis, systemic lupus erythematosus, and associated rheumatologic conditions were identified and each such pt receiving hydroxychloroquine was matched to 2 such pts not receiving hydroxychloroquine (controls). The primary end point was the proportion of pts with PCR-confirmed SARS-CoV-2 infection between March 1 and June 30, 2020 among those receiving long-term hydroxychloroquine therapy versus the propensity-matched patients not receiving hydroxychloroquine. Data analyses indicated that long-term hydroxychloroquine therapy in patients receiving the drug for rheumatic conditions was not associated with a preventive effect against SARS-CoV-2 infection. The incidence of SARS-CoV-2 infection was similar in pts receiving hydroxychloroquine (0.3%; 31 of 10,703 pts) and those not receiving the drug (0.4%; 78 of 21,406 pts). In those who developed active SARS-CoV-2 infection, there were no significant differences in secondary outcomes between the hydroxychloroquine group and control group. 63 Multiple clinical trials to evaluate hydroxychloroquine for treatment of COVID-19 are registered at clinicaltrials.gov, including the following: NCT04342169 NCT04344457 NCT04345692 NCT04353336 Multiple clinical trials to evaluate hydroxychloroquine for prevention of COVID-19 in the healthcare setting or in household contacts of pts with the disease are registered at clinicaltrials.gov, including the following: NCT04303507 NCT04318015</td>

* Updated 10/28/20

** Data are not available on in vitro antiviral activity of peramivir or zanamivir against SARS-CoV-2

| ** NIH COVID-19 Treatment Guidelines** Panel states that, when SARS-CoV-2 and influenza are cocirculating, testing for both viruses is recommended in all hospitalized pts with acute respiratory illness and also recommended in outpatients with acute respiratory illness if results will change clinical management of the pt. Testing is the only way to distinguish between influenza and SARS-CoV-2 and identify coinfection. Treatment of influenza is the same in all pts regardless of SARS-CoV-2 coinfection. If SARS-CoV-2 and influenza are cocirculating, the panel recommends that hospitalized pts suspected of having one or both viral infections should receive oseltamivir for empiric influenza treatment as soon as possible without waiting for influenza testing results; empiric influenza treatment can be de-escalated based on results of testing and intubation status.

** CDC states that, when SARS-CoV-2 and influenza are cocirculating, priority groups for influenza antiviral treatment include pts who are hospitalized with respiratory illness; outpatients with severe, complicated, or progressive respiratory illness; and outpatients at higher risk for influenza complications presenting with any symptoms of acute respiratory illness (with or without fever). CDC recommends oseltamivir for treatment of hospitalized pts with suspected or confirmed influenza and states that oseltamivir, zanamivir, or peramivir may be used for the treatment of influenza in outpatients, taking into account the severity and progression of illness and the presence of complications. |

<td>Remdesivir (Veklury®)</td>
<td>8:18.32</td>
<td>Antiviral</td>
<td>Randomized, double-blind, placebo-controlled trial in hospitalized adults with severe COVID-19 in China (NCT04257656; Wang et al): Pts were randomized 2:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily on days 2-10) or placebo initiated within 12 days of symptom onset. Primary outcome was time to clinical improvement within 28 days after randomization or hospital discharge, whichever occurred first.ITT population included 158 pts treated with remdesivir and 78 pts treated with placebo; 32% of pts also received interferon α-2b, 28% also received LBV/RTV, and 66% also received corticosteroids during hospitalization. Median time to clinical improvement was not significantly different in remdesivir group (21 days) vs placebo group (23 days); 28-day mortality rate was similar in both groups (14 vs 13%). When remdesivir was initiated within 10 days of symptom onset, median time to clinical improvement was numerically shorter (but not statistically significant) compared with placebo group (18 vs 23 days). Duration of invasive mechanical ventilation was numerically shorter (but not statistically significant) in remdesivir group; only a small percentage of pts (0.4%) were on invasive mechanical ventilation at time of enrollment. Remdesivir did not result in significant reduction in SARS-CoV-2 viral load in nasopharyngeal, oropharyngeal, and sputum samples. Remdesivir was discontinued in 18 pts (12%) because of adverse effects. <strong>Note:</strong> Enrollment was terminated before the pre-specified number of pts was attained (lack of available pts); trial was insufficiently powered to detect assumed differences in clinical outcome.</td>
<td>Remdesivir dosage for FDA-labeled indication for treatment of COVID-19 in adults and pediatric patients ≥12 years of age weighing at least 40 kg (lyophilized powder formulation or solution concentrate formulation): Loading dose of 200 mg by IV infusion on day 1, followed by maintenance doses of 100 mg by IV infusion once daily from day 2. For pts requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days. **Emergency use authorization (EUA) for remdesivir: The original EUA issued by FDA on May 1, 2020 permitted use of remdesivir for treatment of COVID-19 in hospitalized adults and children with suspected or laboratory-confirmed COVID-19 and severe disease (defined as oxygen saturation [SpO2] ≤94% on room air or requiring supplemental oxygen, mechanical ventilation, or ECMO); on August 28, 2020, FDA broadened the EUA to allow use of the drug in hospitalized patients irrespective of disease severity. In response to FDA approval of remdesivir for use in adults and pediatric patients ≥12 years of age weighing at least 40 kg, the EUA was reissued on October 22, 2020 to allow continued authorization of the drug (lyophilized powder formulation only) for emergency use in pediatric patients weighing 3.5 to &lt;40 kg and pediatric patients &lt;12 years of age weighing at least 3.5 kg who are hospitalized or in a healthcare setting capable of providing acute care comparable to inpatient hospital care.</td>
<td>The only direct-acting antiviral (DAA) currently approved by FDA for treatment of COVID-19 in certain populations. ** **Available under an emergency use authorization (EUA) for treatment of suspected or laboratory-confirmed COVID-19 in pediatric patients weighing 3.5 to &lt;40 kg and pediatric patients &lt;12 years of age weighing at least 3.5 kg who are hospitalized or in a healthcare setting capable of providing acute care comparable to inpatient hospital care.</td>
</tr>
</tbody>
</table>
severe COVID-19 not receiving mechanical ventilation at study entry; protocol was subsequently modified to include pts 12 years of age or older, add an extension phase, and include a cohort of pts receiving mechanical ventilation. Data for the initial 397 pts not requiring mechanical ventilation at study entry (200 received a 5-day regimen and 197 received a 10-day regimen) indicate similar clinical improvements with both treatment durations after adjusting for baseline clinical status. Pt demographics and clinical characteristics at baseline generally were similar in both groups, although the 10-day group included a higher percentage of pts in the most severe disease categories and a higher proportion of men (who are known to have worse COVID-19 outcomes than women); median duration of symptoms before first dose of remdesivir was similar in both groups (8 or 9 days). At day 14, 129/200 pts (65%) in the 5-day group and 106/197 pts (54%) in the 10-day group achieved clinical improvement (defined as an improvement of at least 2 points from baseline on a 7-point ordinal scale). After adjusting for baseline imbalances in disease severity, data indicate that clinical status at day 14, time to clinical improvement, recovery, and death (from any cause) were similar in both groups. Although eligibility criteria according to the initial study protocol excluded pts receiving invasive mechanical ventilation, 4 pts in the 5-day group and 9 pts in the 10-day group were receiving invasive mechanical ventilation or ECMO (need identified after initial screening and before treatment initiation or pts were accepted as protocol deviations). There were also more pts in the 10-day group (30%) who required high-flow oxygen support at baseline compared with the 5-day group (24%). Post-hoc analysis among pts receiving mechanical ventilation or ECMO at day 5 indicate that, by day 14, 40% of such individuals who had received the 5-day regimen had died compared with 17% of those who had received the 10-day regimen. Treatment with remdesivir beyond 5 days did not appear to improve outcomes among pts who were receiving noninvasive ventilation once daily from day 2. For pts not requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days.

NIH COVID-19 Treatment Guidelines Panel-recommended duration of remdesivir treatment: The NIH panel recommends that hospitalized pts who require supplemental oxygen but do not require high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO, should receive remdesivir for a duration of 5 days or until hospital discharge, whichever comes first. If such pts progress to requiring high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO during such treatment, the panel recommends that the remdesivir course be completed. The panel states that there are insufficient data on the optimal duration of remdesivir treatment for pts who have not shown clinical improvement after a 5-day regimen; some experts would extend the total duration of remdesivir treatment to up to 10 days in these patients.

The EUA for remdesivir requires that the drug be administered by a healthcare provider in an inpatient hospital setting (or alternative care site capable of providing acute care comparable to general inpatient hospital care) via IV infusion at dosages recommended in the EUA. The EUA also requires that healthcare facilities and healthcare providers administering remdesivir comply with certain mandatory record-keeping and reporting requirements (including adverse event reporting to FDA MedWatch).

Healthcare providers should contact Gilead’s sole US distributor (AmerisourceBergen at 800-746-6273) to purchase remdesivir for age-appropriate use under the FDA-approved indication (lyophilized powder formulation or solution concentrate formulation) or the EUA (lyophilized powder formulation only). Healthcare providers should contact AmerisourceBergen or their healthcare provider’s distribution channel for guidance on how to purchase remdesivir. Healthcare providers should report any adverse effects to the FDA MedWatch.

** Concerns regarding variations in remdesivir packaging: The manufacturer is alerting healthcare providers that there are variations in remdesivir packaging and labeling (e.g., use of the tradename Veklury®, expiration dates) depending on whether the drug was originally manufactured for use under the EUA or for commercial use. FDA states that, if patient safety can be assured, they do not intend to object to remdesivir supplies that have labels specifying “for use under Emergency Use Authorization” unless the supplies are labeled as being intended for use under the EUA.

associated with clinical improvement of at least 2 points on day 14. Another subgroup analysis was performed to evaluate outcomes in pts who received concomitant therapy with remdesivir and hydroxychloroquine vs those who received only remdesivir. At a median follow-up of 14 days, the rates and likelihood of recovery were lower in those treated with both drugs (57%) compared with those treated with remdesivir alone (69%). Although concomitant hydroxychloroquine was not associated with increased mortality at 14 days, the overall rate of adverse effects was higher and, after adjusting for baseline variables, the incidence of grade 3-4 adverse events was significantly higher in those treated with both drugs.\textsuperscript{24}

Phase 3 randomized, open-label trial in hospitalized pts with moderate COVID-19 (NCT04292730; GS-US-540-5774; SIMPLE-Moderate) sponsored by the manufacturer (Gilead): Initial study protocol was designed to evaluate safety and antiviral activity of 5- and 10-day regimens of remdesivir (200 mg IV on day 1, followed by 100 mg IV once daily for total of 5 or 10 days) in conjunction with standard of care compared with standard care alone in adults with moderate COVID-19 (i.e., hospitalized with evidence of pulmonary infiltrates and SpO\textsubscript{2} >94% on room air); protocol was subsequently modified to change the primary end point to clinical status on day 11 based on a 7-point ordinal scale, include pts 12 years of age or older, and add an extension phase to include additional pts.\textsuperscript{11, 30} Data for the initial group of adults who received a 5-day regimen of remdesivir with standard care (n=193), 10-day regimen of the drug with standard care (n=193), or standard care alone (n=200) have been published. At day 11, 70, 65, or 61% of pts in the 5-day, 10-day, or standard of care alone group, respectively, had clinical improvement based on at least a 2-point improvement from baseline on a 7-point ordinal scale. Pts in the 5-day remdesivir group had statistically significant higher odds of a better clinical status distribution on the 7-point scale on day 11

either for or against use of remdesivir; however, there may be situations when the drug is appropriate for a hospitalized pt with moderate disease (e.g., pt is at particularly high risk for clinical deterioration). The panel recommends against use of dexamethasone or other corticosteroids in outpatients or hospitalized pts who do not require supplemental oxygen, unless there are other clinical indications for such therapy.\textsuperscript{20} (See Corticosteroids [Systemic] in this Evidence Table.)

The NIH COVID-19 Treatment Guidelines Panel issued guidelines regarding prioritizing use of remdesivir when supplies are limited: The panel recommends the drug be prioritized for use in hospitalized pts with COVID-19 who require supplemental oxygen, but are not on high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO, because efficacy in this pt population has been demonstrated. This recommendation is largely based on data from the phase 3 adaptive trial (NCT04280705; ACTT-1) in hospitalized adults with COVID-19 indicating that the benefit of remdesivir treatment was most apparent in pts who required supplemental oxygen, but did not require high-flow oxygen, noninvasive or mechanical ventilation, or ECMO at baseline. (See Trials or Clinical Experience.)\textsuperscript{20}

Concomitant use of remdesivir and chloroquine or hydroxychloroquine is not recommended;\textsuperscript{26, 36, 41, 46} FDA warns that there is in vitro evidence that chloroquine antagonizes intracellular metabolic activation and antiviral activity of remdesivir.\textsuperscript{26}

Remdesivir clinical drug interaction studies have not been performed to date. In vitro studies indicate remdesivir and its metabolites are substrates and/ or inhibitors of certain drug metabolizing enzymes and transporters; the clinical relevance of these in vitro assessments has not been established.\textsuperscript{46}

<td></td>
<td>than those receiving standard care (odds ratio: 1.65) but the difference was of uncertain clinical importance; the difference in clinical status distribution between pts in the 10-day remdesivir group and the standard care group was not statistically significant. At day 11, 4 deaths were reported in the standard care alone group compared with none in the 5-day group and 2 in the 10-day group. There were no significant differences between the 5- or 10-day remdesivir groups and standard care group for any of the exploratory end points at day 11 (time to 2-point or greater improvement in clinical status, time to 1-point or greater improvement in clinical status, time to recovery, time to modified recovery, time to discontinuation of oxygen support). At day 14, the clinical status of pts in the 5-day and 10-day remdesivir groups was significantly different than that of the standard care group. <strong>Note:</strong> Effect of remdesivir on SARS-CoV-2 viral load was not assessed. Limitations of this study include the open-label design and use of an ordinal scale to evaluate outcomes that was not ideal for detecting differences in pts with moderate COVID-19. 30</td>
<td>Some experts suggest that concomitant use of remdesivir and drugs that are strong inducers of cytochrome P-450 (CYP) isoenzymes (e.g., rifampin) is <strong>not recommended</strong>; remdesivir plasma concentration may be modestly reduced and the clinical relevance of such decreased concentrations is unknown. These experts state that remdesivir plasma concentrations are unlikely to be substantially altered by concomitant use with drugs that are weak to moderate inducers or strong inhibitors of CYP isoenzymes, P-glycoprotein (P-gp), or organic anion transport polypeptide (OATP). 20</td>
<td>Concomitant use of remdesivir and dexamethasone is expected to result in minimal or no reduction in remdesivir exposure. 20</td>

</table>

population). Baseline demographics and clinical characteristics (e.g., age, disease severity, comorbidities at study enrollment, time to initiation of treatment after symptom onset) were similar in both groups. A total of 957 pts (90.1%) had severe disease (i.e., required mechanical ventilation, required supplemental oxygen, had \( \text{SpO}_2 \leq 94\% \) on room air, or had tachypnea with respiratory rate \( \geq 24 \text{ breaths/minute} \)) at study enrollment, and the median time from symptom onset to randomization was 9 days (range: 6-12 days). Final trial data indicated **shorter median time to recovery in the remdesivir group (10 days) vs the placebo group (15 days); recovery rate ratio 1.29.** Those who received remdesivir were more likely to have clinical improvement at day 15 than those who received placebo (odds ratio 1.5). Kaplan-Meier estimates of mortality by day 15 were 6.7% in the remdesivir group vs 11.9% in the placebo group (hazard ratio 0.55); by day 29, mortality was 11.4 and 15.2%, respectively (hazard ratio 0.73). Posthoc analysis of efficacy based on disease severity at enrollment suggested that benefits of remdesivir were most apparent in hospitalized pts receiving low-flow oxygen (recovery rate ratio 1.45); the recovery rate ratio in the subgroup of pts on mechanical ventilation or ECMO at enrollment was 0.98.\(^{42}\) There was no observed benefit of remdesivir compared with placebo in the subgroup with mild to moderate disease (defined as \( \text{SpO}_2 > 94\% \) on room air or a respiratory rate <24 beats/minute without supplemental oxygen) at enrollment; however, the number of pts in this subgroup was relatively small. Although there was no observed difference in time to recovery in subgroups requiring high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO at enrollment, the trial was not powered to detect differences in outcomes within subgroups and there is uncertainty about the effects of remdesivir on the course of COVID-19 in patients who are mechanically ventilated or on ECMO.\(^{20}\)

<td></td>
<td>World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. Interim results (not peer reviewed) have been announced, including results for the remdesivir treatment arm. From March 22 to October 4, 2020, 2750 pts were randomized to receive remdesivir (200 mg on day 1, then 100 mg on days 2-10) and 2725 pts were randomized to remdesivir control (i.e., standard of care). Preliminary data analysis for the intention-to-treat (ITT) population indicated that remdesivir did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for remdesivir in the ITT population was 0.95; 301/2743 pts treated with remdesivir (12.5%) and 303/2708 pts treated with standard of care (12.7%) died.(^4) Data from the manufacturer’s compassionate use program (adults): Preliminary data are available for a cohort of 53 adults from multiple sites in the US, Italy, Japan, and other countries who were hospitalized with severe COVID-19 and received treatment with remdesivir; 40 pts received the full 10-day regimen (200 mg IV on day 1, then 100 mg IV on days 2-10), 10 pts received 5-9 days and 3 pts received less than 5 days of treatment with the drug. At baseline, 30 pts (57%) were receiving mechanical ventilation and 4 (18%) were receiving extracorporeal membrane oxygenation (ECMO). Over a median follow-up of 18 days after first dose, 36 pts (68%) showed clinical improvement based on oxygen-support status and 8 pts (15%) worsened. There were 7 deaths (13%), including 6 pts receiving invasive ventilation. Adverse effects (e.g., increased hepatic enzymes,</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
diarrhea, rash, renal impairment, hypotension) were reported in 32 pts (60%); 12 pts (23%) had serious adverse effects (e.g., multiple organ dysfunction syndrome, septic shock, acute kidney injury, hypotension); 4 pts (8%) discontinued the drug because of adverse effects. **Note:** Data presented for this small cohort of pts offers only limited information regarding efficacy and safety of remdesivir for treatment of COVID-19. There was no control group and, although supportive therapy could be provided at the discretion of the clinician, it is unclear whether pts at any of the various study sites also received other therapeutic agents being used for treatment of COVID-19. In addition, data were not presented regarding the effects of remdesivir on viral load.

**Data from the manufacturer’s compassionate use program (pediatric pts):** The manufacturer announced that preliminary data are available for 77 pediatric pts treated with remdesivir in the compassionate use program. Analysis of day-28 data indicated that 73% of these pediatric pts were discharged from the hospital, 12% remained hospitalized but on ambient air, and 4% had died. There were 39 critically ill pediatric pts who required invasive mechanical ventilation at baseline and 80% of these pts recovered; there were 38 pediatric pts who did not require invasive ventilation and 87% of these pts recovered. No new safety signals were identified for remdesivir in this population.

**Data from the manufacturer’s compassionate use program (pregnant and postpartum women):** The manufacturer announced that preliminary data are available for 86 pregnant and postpartum women treated with remdesivir in the compassionate use program. Analysis of data for these pts (median age 33 years) indicated that 96% of the pregnant women and 89% of the postpartum women achieved improvement in oxygen support levels. Those with more severe illness at baseline achieved similarly high rates of clinical recovery (93 or 89% in those who were pregnant or...

</tr>
</thead>
</table>
| postpartum, respectively). Pregnant women not on invasive oxygen support at baseline had the shortest median time to recovery (5 days), and both pregnant and postpartum women on invasive ventilation at baseline had similar median times to recovery (13 days). No new safety signals were identified for remdesivir in this population; the most common adverse events were due to underlying disease and most laboratory abnormalities were grades 1–2.  

**Phase 2/3 single-arm, open-label trial in pediatric patients (NCT04431453; CARA-VAN):** The manufacturer (Gilead) initiated a trial to evaluate safety, tolerability, pharmacokinetics, and efficacy of remdesivir in pediatric pts (birth to <18 years of age) with laboratory-confirmed COVID-19.  

**Compassionate use access for pregnant women and children <18 years of age:** The manufacturer (Gilead) may accept individual remdesivir compassionate use requests for pregnant women and children <18 years of age with confirmed COVID-19 and severe manifestations of the disease. ([https://rdcu.gilead.com/](https://rdcu.gilead.com/))  

**Compassionate use access (NCT04302766):** May be available for DoD personnel through treatment IND protocol sponsored by US Army Medical Research and Development Command.  

**Phase 3 adaptive, randomized, double-blind trial to compare a regimen of remdesivir alone vs a regimen of remdesivir with baricitinib (NCT04401579; ACTT-2):** This iteration of NIAID’s Adaptive COVID-19 Treatment Trial (ACTT) is evaluating possible benefits of using baricitinib (a Janus kinase [JAK] inhibitor) in conjunction with remdesivir in hospitalized adults with laboratory-confirmed SARS-CoV-2 infection and illness of any duration with at least one of the following: abnormal imaging (chest x-rays, CT scan, etc), SpO2 ≤94% on room air, or requiring supplemental oxygen, mechanical ventilation, or ECMO. Pts are randomized 1:1 to receive

<td>remdesivir (200 mg IV on day 1, then 100 mg IV once daily for the duration of hospitalization up to 10 days total) with either oral baricitinib (4 mg once daily for the duration of hospitalization up to 14 days total) or placebo. The primary outcome measure is time to recovery through day 29 (defined as discharged from the hospital with or without limitations on activities or requiring home oxygen or still hospitalized but not requiring supplemental oxygen and no longer requiring ongoing medical care). Preliminary trial data were announced indicating that use of a combined regimen of remdesivir and baricitinib met the primary end point of reduced time to recovery compared with use of remdesivir alone (median time to recovery was 7 days in those receiving the combined regimen vs 8 days in those receiving remdesivir alone). In addition, preliminary data indicate that the mortality rate at day 29 was 5.1% in those treated with the combined regimen and 7.8% in those treated with remdesivir alone; reduction in mortality was more pronounced in those requiring oxygen. Final data analyses have not been published to date.</td>
<td>Phase 3 adaptive, randomized, double-blind trial to compare a regimen of remdesivir alone vs a regimen of remdesivir with interferon beta-1a (NCT04492475; ACTT3): This iteration of NIAID’s Adaptive COVID-19 Treatment Trial (ACTT) is evaluating possible benefits of using interferon beta-1a in conjunction with remdesivir in hospitalized adults with laboratory-confirmed SARS-CoV-2 infection. Inclusion criteria include evidence of lung involvement (radiographic infiltrates, SpO₂ of 94% or lower on room air, or requiring supplemental oxygen or mechanical ventilation); exclusion criteria include need for ECMO, prior treatment with ≥3 doses of remdesivir, treatment with any interferon preparation within the previous 2 weeks, prior treatment with convalescent plasma or IGIV or various other drugs used for management of COVID-19. Pts will be randomized 1:1 to receive remdesivir (200 mg IV on day 1,</td>

<td>SARS-CoV-2-Specific Monoclonal Antibodies</td>
<td>8:18.24 Monoclonal Antibodies</td>
<td>Monoclonal antibodies (mAbs) used in the treatment or prevention of infectious diseases are engineered versions of antibodies naturally produced by the immune system in response to invading viruses or other pathogens.</td>
<td>Clinical trials have been initiated to evaluate several different SARS-CoV-2-specific mAbs, including the following: <strong>REGN-COV</strong>: Randomized, placebo-controlled, phase 1/phase 2/phase 3 trial sponsored by the manufacturer (Regeneron) to evaluate safety, tolerability, and efficacy of a single IV dose of REGN-COV2 for treatment of COVID-19 in hospitalized adults (NCT04426695). Randomized, placebo-controlled, phase 1/phase 2/phase 3 trial sponsored by the manufacturer (Regeneron) to evaluate safety, tolerability, and efficacy of a single IV dose of REGN-COV2 for treatment of COVID-19 in ambulatory adults (NCT04425629). Enrolled pts were randomized 1:1:1 to receive a single IV infusion of 8 g of REGN-COV2 (high dose), 2.4 g of REGN-COV2 (low dose), or placebo. The manufacturer announced results for the first 275 pts enrolled in this trial and stated that data analysis showed that REGN-COV2 reduced viral load and time to alleviation of symptoms in these outpatients and there was a positive trend in reduction of medical visits; the greatest treatment benefit appeared to be in pts who had not mounted their own effective immune response.</td>
<td>Because mAbs generally have long half-lives, it is likely that only a single dose of the SARS-CoV-2-specific mAbs may be required.</td>
<td>SARS-CoV-2-specific mAbs are not commercially available. Safety and efficacy of investigational SARS-CoV-2-specific mAbs for the treatment or prevention of COVID-19 have not been established. Although results of controlled clinical trials are needed to provide information on safety and efficacy of mAbs that specifically target SARS-CoV-2, it has been suggested that such mAbs may offer some advantages over other immunotherapies used for the treatment of COVID-19 (e.g., COVID-19 convalescent plasma, IGIV) in terms of specificity and safety.</td>
</tr>
<tr>
<td><strong>Updated 10/15/20</strong></td>
<td></td>
<td>mAbs that are specific for certain infectious agents or their toxins (e.g., respiratory syncytial virus, <em>Bacillus anthracis</em>, <em>Clostridioides difficile</em>) have been used for the treatment or prevention of infections caused by these agents. Animal studies evaluating neutralizing mAbs specific for other coronaviruses (SARS-CoV-1, MERS-CoV) have demonstrated benefits in such models. SARS-CoV-2-specific mAbs are designed to directly target the virus and may act as neutralizing antibodies (nAbs). Most SARS-CoV-2-specific mAbs being investigated target epitopes on the spike protein (S protein) of the virus and block the receptor-binding domain (RBD) of the S protein from interacting with human angiotensin-converting enzyme 2 (ACE2), thereby preventing the virus from entering cells and inhibiting viral replication. SARS-CoV-2-specific mAbs potentially could limit or modify SARS-CoV-2 infection and may be effective.</td>

| Umifenovir       | 8:18.92    | Broad-spectrum antiviral with in vitro activity against various viruses, including coronaviruses. Although data limited, in vitro activity against SARS-CoV-1 and SARS-CoV-2 reported. Licensed in China, Russia, Ukraine, and possibly other countries for prophylaxis and treatment of influenza. | **Retrospective cohort study** in 50 adults with COVID-19 in China suggests better viral suppression with umifenovir vs LPV/RTV. All pts received conventional therapy, including interferon α-2b. At 7 days after hospital admission, SARS-CoV-2 was undetectable in 50% of pts treated with umifenovir vs 23.5% treated with LPV/RTV; at 14 days, viral load undetectable in all pts treated with umifenovir vs 44.1% treated with LPV/RTV. Duration of positive SARS-CoV-2 RNA positive test was shorter with umifenovir vs LPV-RTV.  
**Retrospective cohort study** in 33 adults with COVID-19 in China suggests more favorable outcome with LPV/RTV plus umifenovir vs LPV/RTV alone: Primary end point was negative conversion in nasopharyngeal samples and progression or improvement of pneumonia. At 7 days, SARS-CoV-2 undetectable in nasopharyngeal specimens in 12/16 pts (75%) treated with LPV/RTV plus umifenovir vs 6/17 pts (35%) treated with LPV/RTV alone; at 14 days, undetectable in 15/16 pts (94%) treated with both drugs vs 9/17 pts (53%) treated with LPV/RTV alone. At 7 days, chest CT scans were improving in 11/16 pts (69%) treated with both drugs vs 5/17 pts (29%) treated with LPV/RTV alone.  
**Retrospective cohort study** in 81 hospitalized, non-ICU adults with COVID-19 in China found no difference in clearance of SARS-CoV-2 virus between pts receiving umifenovir vs those who did not. At 7 days, SARS-CoV-2 undetectable in pharyngeal specimens in 33/45 pts (73.3%) treated with umifenovir vs 28/36 pts (77.8%) who... | Dosage recommended for treatment of COVID-19 in China: Adults, 200 mg orally 3 times daily for no more than 10 days.  
Dosage used or being investigated in COVID-19 clinical trials: 200 mg orally 3 times daily for duration of 7-10 days or longer.  
Efficacy for the treatment of COVID-19 not established | Not commercially available in the US  
Included in some guidelines for treatment of COVID-19  
Included in the guidelines for the treatment of COVID-19 in China. |

a median of 9 days followed by daily low-dose subcutaneous administration [100 mg twice daily] for 3 additional days to prevent relapse) or low-dose anakinra (100 mg twice daily subcutaneously) and were compared with a historical cohort of patients who did not receive anakinra. At 21 days, high-dose anakinra was associated with reduced CRP levels and progressive improvement in respiratory function in 21 of 29 (72%) of patients; 5 patients (17%) were placed on mechanical ventilation and 3 patients (10%) died. High-dose IV anakinra appeared to be relatively well tolerated. Anakinra was discontinued in the low-dose subcutaneous anakinra group after 7 days because of a lack of improvement in CRP levels and clinical status. In the standard treatment alone group (retrospective cohort), 8 out of 16 patients (50%) showed respiratory improvement at 21 days; 1 patient (6%) was placed on mechanical ventilation and 7 patients (44%) died. 10

**Italy:** Phase 3 randomized, open-label, multicenter trial (NCT04324021) initiated by the manufacturer (Swedish Orphan Biovitrum) to evaluate efficacy and safety of anakinra or emapalumab with standard of care in reducing hyperinflammation and respiratory distress in patients with COVID-19 is recruiting. 3

Numerous other clinical trials evaluating anakinra in the treatment of COVID-19 are planned or under way, mainly in Europe 3

with or without azithromycin is **not** associated with decreased in-hospital mortality.\(^{30,31}\) (See Hydroxychloroquine in this Evidence Table.)

**Open-label, randomized, multicenter trial in adults hospitalized with severe COVID-19 in Brazil (NCT04321278; COALITION II):**

Patients were randomized 1:1 to receive oral azithromycin (500 mg once daily for 10 days) plus standard of care (n=214) or standard of care (control group; n=183). All pts received oral hydroxychloroquine (400 mg twice daily for 10 days) as part of standard of care; concomitant use of corticosteroids, other immunomodulators, antibiotics (no macrolides), and antivirals was allowed. Inclusion criteria required at least one severity criterion (use of oxygen supplementation at more than 4 L/minute, high-flow nasal cannula, noninvasive positive-pressure ventilation, or mechanical ventilation). Exclusion criteria included history of severe ventricular cardiac arrhythmia or QTc ≥480 msec in any ECG performed before randomization. The primary outcome was clinical status at day 15 based on a 6-level ordinal scale that ranged from not hospitalized (1) to death (6); the key secondary outcome was mortality at day 29. Results for the modified intention-to-treat (mITT) population (i.e., those with confirmed COVID-19) indicated that addition of azithromycin to standard of care was not superior to standard of care alone. At day 15, there was no difference in the proportional odds of being in higher categories on the 6-point ordinal scale between the azithromycin group and control group. At day 29, 42% of pts in the azithromycin group and 40% of those in the control group had died. There also was no difference between the groups in the proportion of pts with QTc interval prolongation (20% in azithromycin group and 21% in control group).\(^{34}\)

**Various clinical trials to evaluate azithromycin alone or in conjunction with other drugs for treatment of COVID-19 are registered at clinicaltrials.gov, including the following:**\(^{19}\)

**IDSA recommends against** use of a combined regimen of hydroxychloroquine (or chloroquine) and azithromycin for the treatment of COVID-19 in hospitalized pts.\(^{22}\)

Because azithromycin and 4- aminoquinolines (hydroxychloroquine, chloroquine) are independently associated with QT prolongation, caution is advised if considering use of azithromycin with one of these drugs in pts with COVID-19, especially in outpatients who may not receive close monitoring and in those at risk for QT prolongation or receiving other drugs associated with arrhythmias.\(^{20-22,25-28,33}\)

**NIH panel states that macrolides (including azithromycin) should be used concomitantly with hydroxychloroquine (or chloroquine) only if necessary. In addition, because of the long half-lives of both azithromycin (up to 72 hours) and hydroxychloroquine (up to 40 days), caution is warranted even when the drugs are used sequentially. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving hydroxychloroquine (or chloroquine).**\(^{21}\)

The benefits and risks of a combined regimen of azithromycin and hydroxychloroquine (or chloroquine) should be carefully assessed; if the regimen is used, diagnostic testing and monitoring are recommended to minimize risk of adverse effects, including drug-induced cardiac effects.\(^{20-22,25-28,33}\) (See Hydroxychloroquine in this Evidence Table.)

| Colchicine      | 92:16      | Exerts broad anti-inflammatory and immunomodulatory effects through multiple mechanisms, including inhibition of NOD-like receptor protein 3 (NLRP3) inflammasome assembly and disruption of cytoskeletal functions through inhibition of microtubule polymerization<sup>2,3,5,6</sup>  
May combat the hyper-inflammatory state of COVID-19 (e.g., cytokine storm) by suppressing proinflammatory cytokines and chemokines<sup>2</sup>  
NLRP3 inflammasome activation results in release of interleukins, including IL-1β<sup>3,5,8,11</sup>  
In experimental models of acute respiratory distress syndrome/acute lung injury (ARDS/ALI), the NLRP3 inflammasome had a major role in the development of lung injury<sup>3,11</sup>  
Evaluate the efficacy and safety of baricitinib in hospitalized adults with COVID-19 who have at least one elevated marker of inflammation but do not require mechanical ventilation upon study entry. Targeted enrollment is 400 patients; study will be conducted in the U.S., Europe, and Latin America. Patients in the baricitinib treatment arm will receive an oral dosage of 4 mg daily for up to 14 days or until hospital discharge in addition to their background therapy.  
Other planned clinical trials will evaluate baricitinib in combination with or without an antiviral agent for the treatment of COVID-19 (NCT04346147, NCT04320277, NCT04345289, NCT04321993)<sup>5,10</sup> | Dosage in NCT04326790 (GRECCO-19): Colchicine loading dosage: 1.5 mg followed in 1 hour by 0.5 mg (reduced to a single 1-mg dose in those receiving azithromycin); maintenance dosage: 0.5 mg twice daily (reduced to 0.5 mg once daily in those weighing <60 kg) until hospital discharge or maximum of 21 days<sup>17</sup>  
Dosage in another ongoing trial:  
Colchicine 0.5 mg 3 times daily for 5 days, then 0.5 mg twice daily for 5 days (initial dose is 1 mg if body weight ≥80 kg); dosage is reduced for renal impairment.<sup>18</sup>  
Dosage in NCT04322682: Colchicine 0.5 mg orally twice daily for 3 days, then 0.5 mg once daily for 27 days<sup>1</sup> | Safety and efficacy for treatment of COVID-19 not established  
The potential for toxic doses of colchicine to affect alveolar type II pneumocytes (which may inhibit surfactant release and contribute to ARDS) and increase the risk of multiple-organ failure and disseminated intravascular coagulation (DIC) has been raised as a possible concern with the use of colchicine in COVID-19 patients<sup>14</sup> |

SARS-CoV-1 envelope (E) protein, a viroporin involved in replication and virulence, activates the NLRP3 inflammasome in vitro in Vero E6 cells by forming calcium-permeable ion channels, leading to increased IL-1β production<sup>2,12,13</sup> |

Interim analysis (not peer reviewed) of a single-center, randomized, double-blind, placebo-controlled trial in hospitalized adults with moderate to severe, RT-PCR-confirmed COVID-19 with pneumonia (not requiring ICU admission): Analysis of first 38 patients randomized 1:1 to colchicine or placebo indicated shorter duration of oxygen supplementation (3 vs 7 days) and shorter hospital stay (6 vs 8.5 days) in colchicine group vs placebo group. One patient in each group required ICU admission. Median duration of symptoms prior to treatment was 9 days (colchicine group) or 7 days (placebo group). Colchicine dosage was 0.5 mg 3 times daily for 5 days; then 0.5 mg twice daily for 5 days (initial dose was 1 mg if body weight ≥80 kg); dosage was reduced for renal impairment. Standard concomitant treatment included 7-day azithromycin regimen, up to 10-day hydroxychloroquine regimen, and heparin with or without methylprednisolone (depending on oxygenation status).<sup>18</sup> |

| Dexamethasone (6 mg once daily orally or IV for up to 10 days) plus standard care and 4321 patients were randomized to receive standard care alone. Preliminary data analysis indicates that overall 28-day mortality was reduced in patients receiving dexamethasone compared with those receiving standard care alone with the greatest benefit observed in patients requiring mechanical ventilation at enrollment. Overall, 22.5% of patients receiving dexamethasone and 25.7% of those receiving standard care died within 28 days of study enrollment. In patients receiving dexamethasone, the incidence of death was lower than that in the standard care group among those receiving invasive mechanical ventilation (29.3 vs 41.4%) and among those receiving supplemental oxygen without invasive mechanical ventilation (23.3 vs 26.2%). However, no survival benefit was observed with dexamethasone and there was a possibility of harm in patients who did not require respiratory support at enrollment; the incidence of death in such patients receiving dexamethasone compared with standard care was 17.8 vs 14%, respectively. Dexamethasone was associated with a reduction in 28-day mortality among patients with symptoms for >7 days compared with those having more recent symptom onset. Dexamethasone treatment also was associated with a shorter duration of hospitalization and a greater probability of discharge within 28 days with the greatest effect observed among patients receiving invasive mechanical ventilation at baseline. 24, 32, 33 Note: Data regarding potential adverse effects, efficacy in combination with other treatments (e.g., remdesivir), and efficacy in other patient populations (e.g., pediatric patients and pregnant women) not available to date. 24 Dexamethasone randomized, controlled, open-label, multicenter study (NCT04327401; CoDEX): This trial was conducted to determine whether IV dexamethasone increases the number of ventilator-free days among patients with COVID-19-associated ARDS. The study enrolled adults with COVID-19 and moderate or severe short-acting and administered in 2-4 divided doses daily. 24 Regimens used in early cases of COVID-19 in China were typically methylprednisolone 40-80 mg IV daily for a course of 3-6 days. Some experts suggest that equivalent dosages of dexamethasone (i.e., 7-15 mg daily, typically 10 mg daily) may have an advantage of producing less fluid retention, since dexamethasone has less mineralocorticoid activity. 8 This dosage of dexamethasone is consistent with those used in the DEXA-ARDS trial. 8, 17 However, lower dosages of dexamethasone (i.e., 6 mg once daily for 10 days) were used in the RECOVERY trial. 12, 40 Higher dosages of IV Dexamethasone (i.e., 20 mg once daily for 5 days followed by 10 mg once daily for an additional 5 days or until ICU discharge, whichever came first) were used in the CoDEX trial in patients with COVID-19 and moderate or severe ARDS. 39 Continuous IV infusion of Hydrocortisone: 200 mg/day for 7 days, followed by 100 mg/day for 4 days, and then 50 mg/day for 3 days (total of 14 days) was used in the CAPE COVID study. If a patient’s respiratory and general status sufficiently improved by day 4, a shorter treatment regimen of Hydrocortisone was used at a dosage of 200 mg/day for 4 days followed by 100 mg/day for 2 days and then 50 mg/day for 2 days (total of 8 days). 30 A fixed dosage of IV Hydrocortisone (50 or 100 mg every 6 hours for 7 days) or a shock-dependent regimen of IV hydrocortisone (50 mg every 6 hours for up to 28 days in the presence of clinically evident shock) was used in the REMAP-CAP study. 41 clinical condition of such non-severe patients worsens (e.g., increased respiratory rate, signs of respiratory distress, or hypoxemia), systemic corticosteroids are recommended for treatment. The WHO Guideline Development Group recommends against discontinuing systemic corticosteroids in patients with non-severe COVID-19 who are receiving systemic corticosteroids for chronic conditions (e.g., COPD, autoimmune diseases). 43 Critically ill patients: The Surviving Sepsis Campaign COVID-19 subcommittee (a joint initiative of the Society of Critical Care Medicine and the European Society of Intensive Care Medicine) recommends against the routine use of systemic corticosteroids in mechanically ventilated adults with COVID-19 and respiratory failure (without ARDS). 12 However, these experts generally support a weak recommendation to use low-dose, short-duration systemic corticosteroids in the sickest patients with COVID-19 and ARDS. 12 Based on preliminary findings from the RECOVERY trial, the NIH COVID-19 Treatment Guidelines Panel recommends the use of dexamethasone (6 mg daily for up to 10 days or until hospital discharge, whichever comes first) in patients with COVID-19 who are receiving mechanical ventilation or in those who require supplemental oxygen but are not on mechanical ventilation. The panel recommends against the use of dexamethasone in COVID-19 patients who do not require supplemental oxygen. 24 (See Remdesivir in this Evidence Table for recommendations from the NIH guidelines panel regarding use of dexamethasone with or without remdesivir in COVID-19 patients based on disease severity.) The NIH guidelines panel states that prolonged use of systemic corticosteroids in patients with COVID-19 may increase the risk of reactivation of latent

<tr>
<td>Hydrocortisone randomized, double-blind sequential trial (NCT02517489; CAPE COVID)</td>
<td></td>
<td></td>
<td>ARDS who were receiving mechanical ventilation from 41 ICUs in Brazil. In the dexamethasone treatment arm, 151 patients were randomized to receive dexamethasone (20 mg IV once daily for 5 days followed by 10 mg IV once daily for another 5 days or until ICU discharge) plus standard care; 148 patients were randomized to receive standard care alone. The primary study end point was ventilator-free days (defined as number of days alive and free from mechanical ventilation) during the first 28 days. Preliminary data analysis indicates that use of IV dexamethasone plus standard care was associated with a higher mean number of ventilator-free days (6.6 days) compared with those receiving standard care alone (4 days). Although there was no significant difference in all-cause mortality at 28 days between the treatment groups, the trial was terminated early after results of the RECOVERY trial became available and, therefore, likely underpowered to determine secondary outcomes such as mortality. Dexamethasone was not associated with an increased risk of adverse effects in this study population of critically ill COVID-19 patients.&lt;sup&gt;23&lt;/sup&gt;</td>
<td></td>
<td>infections (e.g., hepatitis B virus [HBV], herpesvirus, strongyloidiasis, tuberculosis). The risk of reactivation of latent infections following a 10-day course of dexamethasone (6 mg once daily) is not well established. When initiating dexamethasone in patients with COVID-19, appropriate screening and treatment to reduce the risk of Strongyloides hyperinfection in those at high risk of strongyloidiasis (e.g., patients from tropical, subtropical, or warm, temperate regions or those engaged in agricultural activities) or fulminant reactivations of HBV should be considered.&lt;sup&gt;24, 37, 38&lt;/sup&gt; The NIH guidelines panel also states that it is not known at this time whether other corticosteroids will have a similar benefit as dexamethasone. However, if dexamethasone is not available, the panel recommends using alternative corticosteroids (e.g., hydrocortisone, methylprednisolone, prednisone).&lt;sup&gt;24&lt;/sup&gt; IDSA suggests the use of corticosteroids over no corticosteroid therapy in hospitalized patients with severe COVID-19 (i.e., defined as patients with SpO&lt;sub&gt;2&lt;/sub&gt; ≤94% on room air and those who require supplemental oxygen, mechanical ventilation, or ECMO). These experts suggest the use of dexamethasone 6 mg orally or IV daily for 10 days or until hospital discharge, whichever comes first, or substitution of equivalent daily dosages of other corticosteroids (e.g., methylprednisolone 32 mg, prednisone 40 mg) if dexamethasone is unavailable. However, IDSA suggests against using corticosteroids in hospitalized patients with COVID-19 without hypoxemia requiring supplemental oxygen.&lt;sup&gt;21&lt;/sup&gt; The WHO Guideline Development Group strongly recommends the use of systemic corticosteroids (e.g., dexamethasone 6 mg orally or IV daily or hydrocortisone 50 mg IV every 8 hours for 7-10 days) over no systemic corticosteroid therapy for the treatment of patients with severe and/or critical COVID-19,</td>

<td></td>
<td>50.7% of patients in the placebo group. The difference between the treatment groups was not statistically significant; however, the study was discontinued early after results of the RECOVERY trial were announced and, therefore, likely underpowered to determine a statistically and clinically important difference in the primary outcome.</td>
<td></td>
<td>Regardless of hospitalization status. This treatment recommendation includes critically ill patients with COVID-19 who could not be hospitalized or receive oxygen supplementation because of resource limitations. This treatment recommendation is less clear for populations under-represented in recent clinical trials (e.g., children, patients with tuberculosis, immunocompromised individuals); however, the risk of not using systemic corticosteroids and depriving such patients of potentially life-saving therapy should be considered. The WHO treatment recommendation does not apply to the following uses of corticosteroids: transdermal or inhaled administration, high-dose or long-term dosage regimens, or prophylaxis.</td>
<td></td>
</tr>
<tr>
<td>Hydrocortisone multicenter, ongoing, international open-label trial using a randomized, embedded multifactorial adaptive platform (NCT02735707; REMAP-CAP): This trial randomized patients to multiple interventions within multiple domains. In the COVID-19 corticosteroid domain, adults from 8 countries with suspected or confirmed COVID-19 following admission to an ICU for respiratory or cardiovascular organ support were randomized to receive a fixed 7-day regimen of IV hydrocortisone (50 or 100 mg every 6 hours), a shock-dependent regimen of IV hydrocortisone (50 mg every 6 hours when shock was clinically evident), or no hydrocortisone or other corticosteroid. The primary study end point was organ support-free days (defined as days alive and free of ICU-based respiratory or cardiovascular support) within 21 days. The 7-day fixed regimen and the shock-dependent regimen of hydrocortisone were associated with a 93 and 80% probability of benefit in terms of organ support-free days compared with no hydrocortisone. However, the trial was discontinued early after results of the RECOVERY trial were announced and no treatment strategy met the prespecified criteria for statistical superiority, precluding definitive conclusions. In addition, serious adverse effects were reported in 2.6% of patients in the study (4 patients receiving the fixed-dosage regimen and 5 patients receiving the shock-dependent regimen compared with 1 patient receiving no hydrocortisone).</td>
<td>Prospective meta-analysis of studies using systemic corticosteroids (i.e., dexamethasone, hydrocortisone, or methylprednisolone) from the WHO Rapid Evidence Appraisal for COVID-19 Therapies (REACT)</td>
<td></td>
<td></td>
<td></td>
<td></td>

</table>

Cytokine storm: There is no well-established or evidence-based treatment for cytokine storm in patients with COVID-19. However, some experts suggest that use of more potent immunosuppression with corticosteroids may be beneficial in such patients. These experts suggest higher dosages of corticosteroids (e.g., IV methylprednisolone 60-125 mg every 6 hours for up to 3 days) followed by tapering of the dose when inflammatory markers (e.g., C-reactive protein levels) begin to decrease.

Septic shock: The effect of corticosteroids in COVID-19 patients with sepsis or septic shock may be different than the effects seen in those with ARDS. The Surviving Sepsis Campaign and NIH suggest the use of low-dose corticosteroid therapy (e.g., hydrocortisone 200 mg daily as an IV infusion or intermittent doses) over no corticosteroid therapy in adults with COVID-19 and refractory shock. Randomized controlled studies evaluating use of corticosteroids (e.g., hydrocortisone, dexamethasone, methylprednisolone, prednisolone) in septic shock suggest a small, but uncertain mortality reduction. Clinicians considering

</thead>
</table>
| Working Group: This meta-analysis pooled data from 7 randomized clinical trials in 12 countries that evaluated the efficacy of corticosteroids in 1703 critically ill patients with COVID-19. The primary outcome was all-cause mortality up to 30 days after randomization to treatment. Administration of systemic corticosteroids was associated with lower all-cause mortality at 28 days compared with usual care or placebo (222 deaths among 678 patients who received corticosteroids and 425 deaths among 1025 patients who received usual care or placebo). The effect of corticosteroids on reduced mortality was observed in critically ill patients who were and were not receiving mechanical ventilation at randomization and also in patients from the RECOVERY trial who required supplemental oxygen with or without noninvasive ventilation but who were not receiving invasive mechanical ventilation at the time of randomization. The odds ratios for the association between corticosteroids and mortality were similar for dexamethasone and hydrocortisone. The optimal dosage and duration of corticosteroid treatment could not be determined from this analysis; however, there was no evidence suggesting that a higher dosage of corticosteroids was associated with greater benefit than a lower dosage. The authors also concluded that there was no suggestion of an increased risk of serious adverse effects associated with corticosteroid use.  
Methylprednisolone open-label, multicenter, randomized, controlled study (NCT04244591): This recently completed trial compared use of methylprednisolone in conjunction with standard care in patients with confirmed COVID-19 infection that progressed to acute respiratory failure; results have not yet been posted.  
Retrospective, observational study of systemic corticosteroid use in patients with COVID-19 from a New York hospital (Keller et al): Data are available for 1806 patients hospitalized with COVID-19 between Mar 11 and Apr 13, 2020. Patients included in the analysis were those treated with corticosteroids for such patients with COVID-19 should balance the potential small reduction in mortality with potential effects of prolonged coronavirus shedding.  
Patients receiving corticosteroid therapy for chronic conditions: NIH states that oral corticosteroids used for the treatment of an underlying condition prior to COVID-19 infection (e.g., primary or secondary adrenal insufficiency, rheumatologic diseases) should not be discontinued. Supplemental or stress dosages of corticosteroids may be indicated on an individual basis in patients with such conditions.  
Rheumatology experts, including members of the American College of Rheumatology COVID-19 Clinical Guidance Task Force, state that abrupt discontinuance of corticosteroid therapy in patients with rheumatologic diseases should be avoided regardless of COVID-19 exposure or infection status. These experts also state that if indicated, corticosteroids should be used at the lowest effective dosage to control manifestations, but also acknowledge that higher dosages may be necessary in the context of severe, vital organ-threatening rheumatologic disease even following COVID-19 exposure.  
Endocrinology experts state that patients with primary or secondary adrenal insufficiency who are receiving prolonged corticosteroid therapy should follow usual steroid “sick day rules” since these individuals may not be able to mount a normal stress response in the event of COVID-19 infection. If such individuals develop symptoms such as fever and a dry continuous cough,

</table>
| systemic corticosteroids (e.g., dexamethasone, hydrocortisone, methylprednisolone, prednisone) within the first 48 hours of hospital admission (140 patients) and those not treated with corticosteroids (1666 patients) as the control group. Treatment and control groups were similar except that corticosteroid-treated patients were more likely to have a history of COPD, asthma, rheumatoid arthritis, or lupus, or to have received corticosteroids in the year prior to admission. Primary goal of the study was to determine whether early systemic corticosteroid treatment was associated with reduced mortality or need for mechanical ventilation. Overall, early use of systemic corticosteroids was not associated with in-hospital mortality or mechanical ventilation. However, there was a significant treatment effect based on C-reactive protein (CRP) levels. Early use of corticosteroids in patients with initial CRP levels of ≥20 mg/dL was associated with a significantly reduced risk of mortality or need for mechanical ventilation (odds ratio: 0.23). Conversely, such treatment in patients with initial CRP levels of <10 mg/dL was associated with a significantly increased risk of mortality or need for mechanical ventilation (odds ratio: 2.64). The authors state that these findings suggest that appropriate selection of COVID-19 patients for systemic corticosteroid treatment is critical to maximize the likelihood of benefit and minimize the risk of harm. **Note:** The limitations of the observational study design should be considered when interpreting these results. Corticosteroid dosages used in patients included in this study not provided. Further study is needed to determine the role of CRP levels in guiding the use of corticosteroid treatment in patients with COVID-19.  

**Dexamethasone, hydrocortisone, or prednisone for treatment of COVID-19 pneumonia:** Registered clinical trials that have been initiated or underway include:  
NCT04344288  
NCT04344730  
NCT04348305  
NCT04359511  

they should immediately double their daily oral corticosteroid dosage and continue with this regimen until the fever subsides.  

These guidelines also apply to patients who are receiving prolonged therapy (> 3 months) with corticosteroids for underlying inflammatory conditions, including asthma, allergy, and rheumatoid arthritis.  
In such patients whose condition worsens or in those experiencing vomiting or diarrhea, treatment with parenteral corticosteroids may be necessary.  
Administration of physiologic stress doses of corticosteroids (e.g., IV hydrocortisone 50-100 mg 3 times daily) and not pharmacologic doses should be considered in all cases to avoid potentially fatal adrenal failure.  
Additional study is needed to determine the optimum corticosteroid stress dosage regimens in patients with COVID-19.  
There is some evidence suggesting that continuous IV infusion of hydrocortisone (following an initial IV bolus dose) may provide more stable circulating cortisol concentrations in patients with adrenal insufficiency and reduce the potentially harmful effects of peak and trough concentrations of cortisol on the immune system.

**Pregnancy considerations:** For pregnant women with COVID-19, the NIH COVID-19 Treatment Guidelines Panel states that a short course of corticosteroids that cross the placenta (i.e., betamethasone, dexamethasone) is routinely used for fetal benefit (e.g., to hasten fetal lung maturity). Given the potential benefit of decreased maternal mortality and the low risk of fetal adverse effects for this short course of corticosteroid therapy, the panel recommends the use of dexamethasone in pregnant women with COVID-19 who are receiving mechanical ventilation or in those who require supplemental oxygen but are not on mechanical ventilation.  

The WHO Guideline Development Group recommends antenatal...

<td>Inhaled corticosteroids may mitigate local inflammation and inhibit virus proliferation.</td>
<td>NCT04360876, NCT04395105 Methylprednisolone studies for treatment of COVID-19 pneumonia or ARDS: Registered clinical trials that have been initiated or underway include: 22 NCT03852537, NCT04263402, NCT04273321, NCT04323592, NCT04329650, NCT04343729, NCT04374071 Methylprednisolone non-randomized pilot study (NCT04355247): Trial has been initiated to evaluate use of the drug for the prevention of COVID-19 cytokine storm and progression to respiratory failure. 22</td>
<td>Initial dosage of orally inhaled ciclesonide used in the published case series from Japan of 3 patients with COVID-19 pneumonia was 200 mcg 2 times daily. If necessary, the dosage was increased to 400 mcg 3 times</td>
<td>Corticosteroid therapy for pregnant women at risk of preterm birth from 24-34 weeks' gestation when there is no clinical evidence of maternal infection and adequate maternal and newborn care are available. In cases where a pregnant woman presents with mild or moderate COVID-19, the clinical benefits of antenatal corticosteroids may outweigh the risk of potential harm to the woman. The balance of benefits and risks for the woman and preterm infant should be considered during the informed decision-making process. Pediatric considerations: The safety and efficacy of dexamethasone or other corticosteroids for COVID-19 treatment have not been sufficiently evaluated in pediatric patients. Importantly, the RECOVERY trial did not include a significant number of pediatric patients, and mortality rates are significantly lower for pediatric patients with COVID-19 than for adult patients with the disease. Therefore, results of this trial should be interpreted with caution for patients &lt;18 years of age. The NIH COVID-19 Treatment Guidelines Panel states that use of dexamethasone may be beneficial in pediatric patients with respiratory disease due to COVID-19 who are receiving mechanical ventilation. Use of dexamethasone in patients who require other forms of supplemental oxygen support should be considered on an individual basis, and is generally not recommended for pediatric patients who require only low levels of oxygen support (i.e., nasal cannula only). Additional studies are needed to evaluate the use of corticosteroids for the treatment of COVID-19 in pediatric patients, including in those with multisystem inflammatory syndrome in children (MIS-C). 24</td>

<td>conditions among outpatient and hospitalized COVID-19 patients resulted in speculation that respiratory treatments, specifically inhaled corticosteroids, may have a protective effect against SARS-CoV-2. Retrospective, observational study of inhaled corticosteroid use in patients with COPD or asthma and associated risk of COVID-19-related death in the UK (Schultze et al): This study was designed to assess the role of routine use of inhaled corticosteroids on COVID-19-related mortality. Data were extracted from primary care electronic health records and linked with mortality data for a cohort of patients with COPD (n = 148,557) and another cohort with asthma (n = 818,490) who were prescribed standard respiratory treatments within the 4 months prior to the index date. In patients with COPD, an increased risk of COVID-19-related death (hazard ratio: 1.39) was reported after adjusting for age and comorbidities among those who were prescribed inhaled corticosteroids combined with a long-acting β-agonist and/ or long-acting antimuscarinic compared with those prescribed a long-acting β-agonist and long-acting antimuscarinic. In patients with asthma, an increased risk of COVID-19-related death (hazard ratio: 1.55) was reported in patients who were prescribed high-dose inhaled corticosteroids compared with those prescribed a short-acting β-agonist only; however, there was no increased risk of death (hazard ratio: 1.14) in asthma patients receiving low- or medium-dose inhaled corticosteroids compared with nonusers of inhaled corticosteroids. Sensitivity analyses suggest there may be other factors driving the increased risk of death observed with use of inhaled corticosteroids, including underlying disease differences between individuals that are not captured in the health records. The results of this study do not support evidence of benefit or harm with routine use of inhaled corticosteroids on COVID-19-related mortality among individuals with COPD or asthma. A small case series from Japan observed possible clinical benefit in 3 patients with daily. The authors suggested continued use of ciclesonide oral inhalation for about 14 days or longer. Panel also states that no studies to date have investigated the relationship between inhaled corticosteroids in patients with acute respiratory infections due to coronaviruses. Randomized controlled clinical studies are needed to assess the benefits of inhaled corticosteroids for treatment of COVID-19 in patients with and without chronic respiratory conditions.</td>

<td>Inhaled prostacyclins (e.g., epoprostenol, iloprost)</td>
<td>48:48 Vasodilating Agents</td>
<td>Selective pulmonary vasodilators; may be useful in the adjunctive treatment of acute respiratory distress syndrome (ARDS), a complication of COVID-19</td>
<td>There are currently no published studies specifically evaluating use of inhaled prostacyclins in COVID-19 patients. In patients with ARDS, inhaled prostacyclins have been shown to substantially reduce mean pulmonary artery pressure and improve oxygenation; however, data demonstrating clinical benefit (e.g., mortality reduction) are lacking. A phase 2, open-label study (ILOCVID; NCT04445246) evaluating use of inhaled iloprost in adults with suspected or confirmed COVID-19 has been initiated. A phase 2, open-label study (VPCOVID; NCT04452669) evaluating inhaled epoprostenol delivered via a dedicated delivery system (VentaProst) in patients with COVID-19 requiring mechanical ventilation has been initiated. Various dosages of inhaled epoprostenol have been used in patients with ARDS: Dosages up to 50 ng/kg per minute (titrated to response) have been used in clinical studies. To provide a clinically important increase in PaO₂ and reduction in pulmonary artery pressure, data from these studies suggest that the most effective and safe dosage appears to be 20–30 ng/kg per minute in adults and 30 ng/kg per minute in pediatric patients. Dosage of inhaled iloprost that will be evaluated in the phase 2, open-label study (NCT04445246) is 20 mcg every 8 hours for 5 days (delivered by nebulization).</td>
<td></td>
<td>The Surviving Sepsis Campaign states that due to the lack of adequately powered randomized controlled studies, a recommendation cannot be made for or against the use of inhaled prostacyclins in COVID-19 patients with severe ARDS. The NIH COVID-19 Treatment Guidelines Panel and the Surviving Sepsis Campaign state that a trial of inhaled pulmonary vasodilator may be considered as rescue therapy in mechanically ventilated adults with COVID-19, severe ARDS, and hypoxemia; if no rapid improvement in oxygenation is observed, the patient should be tapered off treatment.</td>

<td>Interferons</td>
<td>8:18.20 Interferons</td>
<td>Updated 10/28/20</td>
<td>Interferons (IFNs) modulate immune responses to some viral infections; in vitro studies indicate only weak induction of IFN following SARS-CoV-2 infection, and a possible role for IFNs in prophylaxis or early treatment of COVID-19 has been suggested to compensate for possibly insufficient endogenous IFN production.</td>
<td>Only limited clinical trial data available to date specifically evaluating efficacy of IFNs for treatment of COVID-19. For information on additional studies including IFN alfa or IFN beta as a component of combination therapy (e.g., background regimen), see antiviral entries in this Evidence Table. Clinical trials are currently evaluating IFN beta-1a or IFN beta-1b, generally added to other antivirals, for treatment of COVID-19, including: NCT04492475 (IFN beta-1a) NCT04465695 (IFN beta-1b) NCT04494399 (IFN beta-1b) NCT04324463 (IFN beta) NCT04343768 (IFN beta-1a, IFN beta-1b) Open-label, randomized study in Hong Kong in hospitalized adults with COVID-19, mainly mild disease (NCT04276688): IFN beta-1b 8 million units was given sub-Q on alternate days for 1, 2, or 3 doses (when initiated on day 5-14 days, 3-4, or 1-2, respectively, following symptom onset) in conjunction with 14-day regimen of LPV/RTV and ribavirin. ** In an open-label, randomized study in hospitalized adults with severe COVID-19, IFN beta-1b 250 mcg was given sub-Q every other day for 2 weeks. ** In the SOLIDARITY study, most IFN -treated patients received three 44-mcg doses of IFN beta-1a sub-Q over 6 days. In an open-label, randomized study in hospitalized adults with severe COVID-19, IFN beta-1a 12 million units was given sub-Q 3 times weekly for 2 weeks. IFN alfa: Chinese guidelines suggest IFN alfa dosage of 5 million units (or equivalent) twice daily via atomization inhalation for treatment of COVID-19.</td>
<td>Efficacy and safety of IFNs for treatment or prevention of COVID-19 not established. Relative effectiveness of different IFNs against SARS-CoV-2 not established. NIH COVID-19 Treatment Guidelines Panel recommends against use of IFNs for treatment of severe or critical COVID-19, except in the context of a clinical trial. The panel also states there are insufficient data to recommend either for or against use of IFN beta for the treatment of early (i.e., &lt;7 days from symptom onset) mild or moderate COVID-19. No benefit was observed with use of IFNs for treatment of other severe or critical coronavirus infections (SARS, MERS), and toxicity of IFNs outweighs the potential for benefit. IFNs may have antiviral activity early in the course of SARS-CoV-2 infection; however, there are insufficient data to assess the potential benefit of IFN use during early disease versus the risk of toxicity. Survival Sepsis Campaign COVID-19 subcommittee states that there is insufficient evidence to issue a recommendation on use of interferons, alone or in combination with antivirals, in critically ill adults with COVID-19. Interferon alfa via atomization inhalation is included in Chinese guidelines as a possible option for treatment of COVID-19.</td>

<td>Type 3 IFNs (IFN lambda)</td>
<td></td>
<td>are thought to provide important immunologic defense against respiratory viral infections&lt;sup&gt;1,4,6,7,19&lt;/sup&gt; and may have less potential than type 1 IFNs to produce systemic inflammatory response, including inflammatory effects on respiratory tract;&lt;sup&gt;4,7,19&lt;/sup&gt; IFN lambda receptor is expressed mainly on epithelial (including respiratory epithelial) cells and neutrophils, and is distinct from the ubiquitous type 1 IFN receptor;&lt;sup&gt;2,4,7,19&lt;/sup&gt; despite different receptors and expression patterns, type 1 and type 3 IFNs activate similar signaling cascades;&lt;sup&gt;4,7,19&lt;/sup&gt; unknown whether limited receptor distribution might also affect efficacy&lt;sup&gt;4&lt;/sup&gt;</td>
<td>Regimen of IFN beta-1b (250 mcg sub-Q every other day for 2 weeks) plus Iran national protocol medications was compared with national protocol alone (control). Protocol included a 7- to 10-day regimen of lopinavir/ritonavir or atazanavir/ritonavir and hydroxychloroquine. All patients required respiratory support (mainly oxygenation through facemask [80%]) but none were intubated at baseline. Median time from symptom onset to randomization was 8 days. Total of 80 patients were randomized (40 to each treatment group); analyses were based on data for 33 patients per treatment group after exclusion of those who withdrew consent, were enrolled in another study, or received &lt;4 IFN doses. Median time to clinical improvement (defined as ≥2-category improvement in a 6-category ordinal scale) was shorter in the IFN group than in the control group (9 vs 11 days). Total of 80 patients were randomized (40 to each treatment group); analyses were based on data for 33 patients per treatment group after exclusion of those who withdrew consent, were enrolled in another study, or received &lt;4 IFN doses. Median time to clinical improvement (defined as ≥2-category improvement in a 6-category ordinal scale) was shorter in the IFN group than in the control group (9 vs 11 days). A smaller proportion of IFN-treated patients required ICU admission (42 vs 67%). There was no difference in duration of hospitalization, intubation rate, length of ICU stay, or all-cause 28-day mortality.</td>
<td>Peginterferon lambda-1a:&lt;br&gt;For treatment of COVID-19 in adults (NCT04354259, NCT04388709): Peginterferon lambda-1a 180 mcg sub-Q; number of doses (1 dose or 2 doses given 1 week apart) depends on the protocol.&lt;sup&gt;5&lt;/sup&gt; Peginterferon lambda-1a 180 mcg sub-Q; number of doses (1 dose or 2 doses given 1 week apart) depends on the protocol.</td>

**mortality. NOTE:** Total of 92 patients were randomized; results are based on the 42 IFN beta-1a-treated patients and 39 control patients who completed the study. Diagnosis of COVID-19 was based on RT-PCR testing (64%) or clinical manifestations/imaging findings (36%). Other concomitant therapies included corticosteroids and immune globulin (IFN beta-1a group: 62 and 36%, respectively; control group: 44 and 26%, respectively). Patients were recruited from general, intermediate, and ICU wards; 45% of the IFN beta-1a-treated patients and 59% of the control patients were admitted to ICU; 36 and 44%, respectively, required invasive mechanical ventilation. Mean time from symptom onset to treatment initiation was 11.7 days for the IFN beta-1a group and 9.3 days for the control group. **

** Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. Interim results (not peer reviewed) have been announced, including results for the IFN beta-1a treatment arm. From March 22 to October 4, 2020, 2063 patients were randomized to receive IFN (given in conjunction with lopinavir and ritonavir [n = 651] or standard of care [n = 1412]) and 2064 patients were randomized to IFN control (either lopinavir and ritonavir [n = 679] or standard of care [n = 1385]). Most IFN-treated patients received three 44-mcg doses of IFN beta-1a sub-Q over 6 days; where IV IFN was available, patients on high-flow oxygen, ventilators, or ECMO received 10 mcg IV once daily for 6 days. Preliminary data analysis for the intention-to-treat (ITT) population indicated that IFN did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did...

|         |            |           | not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for IFN in the ITT population was 1.16 overall and 1.12 without concomitant lopinavir and ritonavir; 243/2050 patients treated with IFN (12.9%) and 216/2050 patients treated with standard of care (11%) died. About one-half of the patients randomized to receive IFN or IFN control received corticosteroids; the investigators stated that this did not appear to affect the death rate ratio. The clinical relevance of the difference in the pharmacokinetic profiles of sub-Q and IV IFN is unclear. 23, 24 | ** Phase 2, randomized, double-blind, placebo-controlled study (NCT04385095; SG016) evaluating SNG001 (inhaled IFN beta-1a) in patients with COVID-19: Manufacturer released unaudited 6-month interim results for the in-hospital portion of the study. The intention-to-treat population for the interim analysis included 48 patients treated with SNG001 and 50 patients given placebo (announcement did not provide SNG001 dosage, concomitant treatments, or patient characteristics). Hazard ratio for time to recovery and odds ratios for recovery and for improvement across WHO ordinal scale for clinical improvement favored SNG001 over placebo. The study has been extended to include 120 patients in the home setting. 16, 22, 27 | Aerosolized IFN alfa (not commercially available in U.S.) has been used in China in children and adults for treatment of COVID-19, 13, 24, 25 but limited clinical data presented to date. 11 In a retrospective study of 77 hospitalized adults with moderate COVID-19 disease who received aerosolized IFN alfa-2b (5 million units twice daily) (n = 7), umifenovir (Arbidol®) (n = 24), or both drugs (n = 46), time from symptom onset to negative RT-PCR result in throat swab appeared to be shorter in those receiving IFN alfa-2b alone or in combination with umifenovir compared with those receiving umifenovir alone; this exploratory study was small and nonrandomized, and treatment groups were of unequal size and

<td>Nitric oxide (inhaled)</td>
<td>48:48 Vasodilator</td>
<td>Selective pulmonary vasodilator with bronchodilatory and vasodilatory effects in addition to other systemic effects mediated through cGMP-dependent or independent mechanisms; may be useful for supportive treatment of acute respiratory distress syndrome (ARDS), a complication of COVID-19. Also has been shown to have antiviral effects. In vitro evidence of direct antiviral activity against severe acute respiratory syndrome coronavirus (SARS-CoV-1). In a small pilot study (Chen et al.) conducted during the SARS outbreak, treatment with inhaled nitric oxide was found to reverse pulmonary hypertension, improve severe hypoxia, and shorten the duration of ventilatory support in critically ill SARS patients. Genetic similarity between SARS-CoV and SARS-CoV-2 suggests potential benefit in patients with COVID-19. In the Chen et al. study in severe SARS patients, inhaled nitric oxide therapy was given for ≥3 days (30 ppm on day 1, followed by 20 and 10 ppm on days 2 and 3, respectively, then weaned on day 4; therapy was resumed at 10 ppm if deteriorating oxygenation occurred). Various dosing protocols using different methods of delivery are being evaluated in ongoing studies in COVID-19 patients.</td>
<td>Randomized controlled studies of inhaled nitric oxide in ARDS patients have generally demonstrated modest improvements in oxygenation, but no effect on mortality and possible harm (e.g., renal impairment). Experience with inhaled nitric oxide specifically in COVID-19 patients is limited. In a published case report, improvement in PaO(_2) and oxygen saturations was observed after administration of inhaled nitric oxide in a 12-year-old patient with COVID-19 and severe thrombocytopenia who required mechanical ventilation; the dose of nitric oxide was not reported and the patient was treated with various other therapies. Another case report described use of inhaled nitric oxide (obtained through an emergency investigational new drug application) in an outpatient setting to treat exacerbations of pulmonary arterial hypertension in a 34-year-old patient with concomitant COVID-19; however, the generalizability of this case study finding is limited. In a small case series, administration of inhaled nitric oxide (20 ppm for 30 minutes initially, with option to extend duration if response observed) to 10 mechanically ventilated patients with severe COVID-19 had a negligible effect on oxygenation (i.e., PaO(_2) and PaO(_2~/\text{FiO}_2) did not change substantially). Another report described the use of inhaled nitric oxide (25 ppm) in 16 mechanically ventilated COVID-19 patients with refractory hypoxemia and/or right ventricular dysfunction. Overall, nitric oxide...</td>
<td></td>
<td>The NIH COVID-19 Treatment Guidelines Panel and the Surviving Sepsis Campaign recommend against the routine use of inhaled nitric oxide in mechanically ventilated adults with COVID-19 and ARDS. These experts state that a trial of inhaled pulmonary vasodilator may be considered as rescue therapy in mechanically ventilated adults with COVID-19, severe ARDS, and hypoxemia; however, if no rapid improvement in oxygenation is observed, the patient should be tapered off treatment.</td>

\(^a\)IV infusion: China recommends an initial dose of 4–8 mg/kg infused over more than 60 minutes. If initial dose not effective, may administer second dose (in same dosage as initial dose) after 12 hours. No more than 2 doses should be given; maximum single dose is 800 mg. US/Global randomized, placebo-controlled trial (manufacturer sponsored; COVACTA): Will evaluate an initial IV infusion of 8 mg/kg (up to a maximum dose of 800 mg); one additional dose may be given if symptoms worsen or show no improvement.

\(^b\)Updated 9/10/20

\(^c\)Tocilizumab may prevent progression to severe COVID-19 by restoring T-cell functionality. \(^7\)

\(^1\)In preliminary data from a non-peer-reviewed, single-arm, observational Chinese trial (Xu et al.) involving 21 patients with severe or critical COVID-19 infection, patients demonstrated rapid fever reduction and a reduced need for supplemental oxygen within several days after receiving tocilizumab (initially given as a single 400-mg dose by IV infusion; this dose was repeated within 12 hours in 3 patients because of continued fever). \(^3\)

\(^2\)In a retrospective, observational study in China (Luo et al.) involving 15 patients moderately to critically ill with COVID-19, tocilizumab (80-600 mg per dose) was given, and was used in conjunction with methylprednisolone in 8 of the patients. About one-third of the patients received 2 or more doses of tocilizumab. Elevated C-reactive protein (CRP) levels rapidly decreased in most patients following treatment, and a gradual decrease in IL-6 levels was noted in patients who stabilized following tocilizumab administration. Clinical outcomes were equivocal. \(^10\)

\(^3\)A single-center, retrospective observational study of 20 kidney transplant recipients in Italy with COVID-19 hospitalized for pneumonia included 6 patients who received tocilizumab. Half of the patients experienced reduced oxygen requirements and 2 (33%) showed improved radiologic findings following administration; 2 (33%) of the 6 tocilizumab-treated patients died. \(^12\)

Zhang et al. from China reported on a patient with COVID-19 and multiple myeloma who appeared to be successfully treated with tocilizumab 13.

Currently, there are no well-controlled published studies on the efficacy and safety of tocilizumab for the treatment of COVID-19; however, numerous clinical trials are planned or under way globally 1, 5, 7, 8.

France: An open-label, phase 2, randomized clinical trial (CORIMUNO-TOCI, NCT04331808) is under way at Assistance Publique – Hôpitaux de Paris hospitals in Paris. Interim results from this study have been released in a press release (non-peer-reviewed). Sixty-five out of 129 adults with moderate to severe COVID-19 pneumonia not requiring intensive care upon admission were randomized to receive tocilizumab 8 mg/kg (1–2 doses) along with standard of care, and 64 patients were randomized to receive standard of care alone. A significantly lower proportion of the patients in the tocilizumab arm attained the primary outcome of need for ventilation or death at day 14. Results of this study will be submitted for publication in a peer-reviewed journal 15, 16. | | |

<tr>
<td>Zinc</td>
<td></td>
<td>Trace mineral involved in immune function, including antibody and white blood cell production; an important cofactor for many enzymes; 1,3 may improve wound healing 5. Zinc deficiency increases pro-inflammatory cytokine concentrations (interleukin-1 [IL-1], IL-6, TNF alpha) and decreases antibody production; zinc supplementation increases the ability of polymorphonuclear cells to fight infection 5. Possible antiviral activity; zinc appears to inhibit virus RNA polymerase activity and viral replication in an in vitro and cell culture model of severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1). 1,7 High-dose zinc supplementation reduced the duration but not severity of common cold symptoms compared with placebo in a meta-analysis. 1,3,7 Zinc enhances cytotoxicity and induces apoptosis when used in vitro with a zinc ionophore (e.g., chloroquine): chloroquine can enhance intracellular zinc uptake in vitro 7. Elderly patients and patients with certain concurrent medical conditions are at higher risk of zinc deficiency 2,3,8.</td>
<td>No evidence from controlled trials that zinc is effective in the prevention or treatment of COVID-19. 5,6 Because of its role in immune function and potential to decrease coronavirus replication, zinc is being evaluated in a number of clinical trials in both the prophylaxis and treatment of COVID-19, sometimes in combination with other supplements (including vitamin C, vitamin D, and selenium) and drugs (including hydroxychloroquine) 1,2,5,6. Retrospective observational study in New York City (Carlucci et al; non-peer-reviewed): Data were collected from electronic medical records to compare outcomes between hospitalized patients with COVID-19 who received hydroxychloroquine, azithromycin, and zinc (411 patients) and those who received hydroxychloroquine and azithromycin alone (527 patients). Zinc was given as a zinc sulfate 220-mg capsule (50 mg of elemental zinc) twice daily for 5 days. The addition of zinc did not affect the length of hospitalization, duration of ventilation, or duration of ICU stay, but patients in the treatment group that included zinc were discharged home more frequently and the need for ventilation, ICU admission, and mortality or transfer to hospice for patients not admitted to the ICU were all reduced in univariate analyses. After adjusting for the timing of when zinc was added to the protocol, findings remained significant for increased frequency of being discharged home and reduction in mortality or transfer to hospice in the zinc-treated patients. Because of the study design and its limitations, the authors state that this study should not be used to guide clinical practice, but that the observations do support initiation of randomized controlled trials investigating zinc in patients with COVID-19. 10</td>
<td>Zinc Recommended Dietary Allowance (RDA): Adult males: 11 mg/day; adult females: 8 mg/day. Some clinicians have recommended an elemental zinc intake of 30-50 mg/day in the short-term treatment of influenza and coronavirus infections. 1,4 Appropriate dosage regimens not established in either the prophylaxis or treatment of COVID-19; various supplementation regimens being evaluated in clinical trials, with a maximum dosage of zinc sulfate of 220 mg (50 mg of elemental zinc) twice daily. 2,5,6,9,10 Oral zinc supplementation likely safe in dosages up to 40 mg of elemental zinc daily in adults; safety of dosages exceeding those used in the management of the common cold not known. 3,6,8</td>
<td>Despite some anecdotal claims in the media that zinc is effective in treating COVID-19,6 unclear whether zinc supplementation is beneficial in the prophylaxis and/or treatment of COVID-19; further study is needed 1,3,6. NIH COVID-19 Treatment Guidelines Panel states that there are insufficient clinical data to recommend either for or against use of zinc in the treatment of COVID-19.9 NIH COVID-19 Treatment Guidelines Panel recommends against using zinc supplementation above the RDA for the prevention of COVID-19, except in a clinical trial. Zinc concentrations are difficult to measure accurately since it is distributed as a component of various proteins and amino acids.9 Adverse effects may include nausea (possibly dose dependent), vomiting, and changes in taste.1,6,7,8 Long-term zinc supplementation may cause copper deficiency with adverse hematologic and neurologic effects; zinc supplementation for as long as 10 months has been associated with copper deficiency.9 Intransal administration should be avoided because of reports of prolonged or permanent loss of the sense of smell; intransal zinc formulations are no longer commercially available in the US.6,8 Potential for interactions with iron and copper, certain antibiotics (e.g., quinolones, tetracyclines), and other medications.8</td>

**ACE Inhibitors, Angiotensin II Receptor Blockers (ARBs)**  
*Updated 10/1/20* | 24:32 Renin-Angiotensin-Aldosterone System Inhibitor | **Hypothetical harm:** Human pathogenic coronaviruses bind to their target cells through angiotensin-converting enzyme 2 (ACE2).1, 4-6 Expression of ACE2 may be increased in patients treated with ACE inhibitors or ARBs.1, 4-6 Increased expression of ACE2 may potentially facilitate COVID-19 infections.7 **Hypothetical benefit:** ACE inhibitors or ARBs may have a protective effect against lung damage or may have paradoxical effect in terms of virus binding.1, 3, 6 | Data are lacking; no evidence of harm or benefit with regards to COVID-19 infection.1-3, 9 |  | American Heart Association (AHA), American College of Cardiology (ACC), Heart Failure Society of America (HFSA), and European Society of Cardiology (ESC) recommend continuation of treatment with renin-angiotensin-aldosterone system (RAAS) antagonists in those patients who are currently prescribed such agents.2, 3 These experts state there is a lack of experimental or clinical data demonstrating beneficial or adverse outcomes among COVID-19 patients receiving ACE inhibitors or ARBs. Further study is needed.2, 3 NIH COVID-19 Treatment Guidelines Panel states patients who are receiving an ACE inhibitor or ARB for cardiovascular disease (or other indications) should continue receiving these drugs. The panel recommends against use of ACE inhibitors or ARBs for the treatment of COVID-19 except in the context of a clinical trial. These experts state there is a lack of sufficient clinical evidence demonstrating that ACE inhibitors or ARBs have any impact on the susceptibility of individuals to SARS-CoV-2 or on the severity or outcomes of COVID-19 infection.9 Patients with cardiovascular disease are at an increased risk of serious COVID-19 infections.1, 4 Abrupt withdrawal of RAAS blockers (including ACE inhibitors, ARBs) and the risk of COVID-19: Study included data obtained from a regional healthcare database in the Lombardy region of Italy for 6272 case pts with confirmed severe COVID-19 acute respiratory syndrome from Feb 21 to Mar 11, 2020 who were...**

---

Updated 10-28-20. The current version of this document can be found on the ASHP COVID-19 Resource Center. This work is licensed under a Creative Commons Attribution-NonCommercial 4.0 International License.
matched to 30,759 controls based on sex, age, and place of residence. Information about use of selected drugs and clinical profiles was obtained from regional healthcare databases. Use of ACE inhibitors or ARBs was more frequent in patients with COVID-19 than among controls because of their higher prevalence of cardiovascular disease. Percentage of patients receiving ACE inhibitors was 23.9% for case pts and 21.4% for controls. Percentage of patients receiving ARBs was 22.2% and 19.2% for case and control pts, respectively. The authors concluded that there was no evidence that treatment with ACE inhibitors or ARBs significantly affected the risk of COVID-19 or altered the course of infection or resulted in more severe disease.  

**Large, multinational, retrospective study** analyzed outcome data for hospitalized pts with confirmed COVID-19 to evaluate the relationship between cardiovascular disease and preexisting treatment with ACE inhibitors or ARBs with COVID-19 (Mehra et al; now retracted): Original publication included multinational data for 8910 pts hospitalized with COVID-19 between Dec 20, 2019 and Mar 15, 2020 that were obtained from a global healthcare data collaborative. The authors concluded that those data confirmed previous observations suggesting that underlying cardiovascular disease is independently associated with an increased risk of death in hospitalized pts with COVID-19. They also stated that they were not able to confirm previous concerns regarding a potential harmful association of ACE inhibitors or ARBs with in-hospital mortality.  

**Note:** This published study has now been retracted by the publisher at the request of the original authors. Concerns were raised with respect to the veracity of the data and analyses that were the basis of the authors’ conclusions.  

Clinical trials underway (losartan): Initiation of losartan in adults with COVID-19 requiring hospitalization; primary outcome measure: sequential organ failure assessment (SOFA) respiratory score. (NCT04312009).

The EUA states that COVID-19 convalescent plasma should not be considered a new standard of care for the treatment of patients with COVID-19. FDA states that adequate and well-controlled randomized trials remain necessary to determine optimal product attributes and to identify appropriate subpopulations for its use and that ongoing clinical trials of COVID-19 convalescent plasma should not be amended based on issuance of the EUA. The NIH COVID-19 Treatment Guidelines Panel states that there are insufficient data to recommend for or against the use of convalescent plasma in patients with COVID-19. The Surviving Sepsis Campaign COVID-19 subcommittee suggests that convalescent plasma not be used routinely in critically ill adults with COVID-19 because efficacy and safety not established and uncertainty surrounding optimal preparation of convalescent plasma. Appropriate criteria for selection of patients to receive investigational COVID-19 convalescent plasma, optimal time during the course of the disease to receive such therapy, and appropriate dosage (e.g., volume, number of doses) not determined. Current data suggest that convalescent plasma is more effective if given during the early course. |

<td>convalescent plasma transfusions 10-22 days after hospital admission. Following the transfusions, body temperature normalized within 3 days in 4/5 patients, sequential organ failure assessment (SOFA) scores improved in all patients (decreased from initial scores of 2-10 to 1-4 on day 12), titers of SARS-CoV-2 IgG, IgM, and neutralizing antibody increased in all patients, and viral loads decreased and became negative within 12 days. 10 Retrospective observational study in China (Zeng et al): 6 critically ill adults with COVID-19 were treated with convalescent plasma at a median of 21.5 days after first detection of viral shedding. Although viral clearance was observed in all patients following transfusion, death occurred in 5 of 6 patients. 10 Uncontrolled descriptive study in China (Ye et al): 6 adults with COVID-19 received convalescent plasma at a relatively late stage of the disease (most patients received 2 or 3 plasma transfusions); various laboratory, radiologic, and clinical improvements were reported. 18 Uncontrolled case series in China (Chen et al; non-peer-reviewed): 16 adults with COVID-19 as determined by a SARS-CoV-2 nucleic acid amplification (NAA) test and rapidly progressive, severe, or life-threatening disease received ABO-compatible COVID-19 convalescent plasma (up to 2-3 IV transfusions; each transfusion 200 – 400 mL); no minimum titer of neutralizing antibody was specified for the convalescent plasma. Patients also received multiple other treatments (e.g., antivirals, antibacterials, traditional Chinese medicine). The average time from symptom onset to plasma transfusion was 23 days. Prior to convalescent plasma transfusion, 10/16 patients had consistently positive SARS-CoV-2 results. Time to SARS-CoV-2 negativity following convalescent plasma transfusion was 2-8 days in 8/10 patients, including 5 critically ill patients and 3 with severe COVID-19 disease. SARS-CoV-2 positivity persisted in 2 critically ill patients; of the disease. 1, 2, 16, 17, 20, 24, 37, 38</td>

</table>

Optimal timing of donor plasma collection in relation to recovery from COVID-19, most appropriate methods of antibody testing, and minimum titers of SARS-CoV-2 antibody in convalescent plasma that may be associated with clinical benefits in pts with COVID-19 not determined. 11-13 Current data suggest that the clinical benefit is greatest when high-titer convalescent plasma is given early in the course of the disease. 36, 37, 38 Logistics of obtaining, processing, storing, and distributing COVID-19 convalescent plasma evolving. 1-5, 11, 14, 15 FDA does not collect COVID-19 convalescent plasma and does not provide such plasma; healthcare providers and acute care facilities obtain COVID-19 convalescent plasma from FDA-registered establishments. 11 Analysis of key safety indicators in 20,000 adults who participated in a US FDA Expanded Access Program (NCT04338360) suggests that IV transfusion of COVID-19 convalescent plasma is safe in hospitalized patients with COVID-19; however, potential risks associated with COVID-19 convalescent plasma therapy (e.g., inadvertent transmission of other infectious agents, allergic reactions, thrombotic complications, transfusion-associated circulatory overload, transfusion-related acute lung injury [TRALI], antibody-dependent enhancement of infection) and steps to mitigate such risks not fully determined and require further evaluation. 1, 5, 9, 23, 24, 25 May be contraindicated in patients with a history of severe allergic reactions or anaphylaxis to plasma transfusion. 38 Safety and effectiveness in pediatric patients have not been evaluated; a decision to use COVID-19 convalescent plasma in patients <18 years of age should be based on an individualized assessment of risks and benefits. 38 |

</tbody>
</table>

**Uncontrolled case series in US (Salazar et al):** 316 adults with severe and/or life-threatening COVID-19 disease received convalescent plasma (one or two units) in addition to multiple other treatments (e.g., antivirals, anti-inflammatory agents). At the time of an interim analysis, outcomes of 136 convalescent plasma recipients who reached day 28 post-transfusion were compared with two sets of propensity score-matched controls at 28 days after admission. These data suggested a trend toward benefit of convalescent plasma, particularly in patients who were transfused early (i.e., within 72 hours of admission) with high-titer convalescent plasma (i.e., anti-spike protein receptor binding domain titer ≥1:1350). [25, 48]

**Cochrane systematic review:** Analysis of 20 published studies (1 RCT, 3 controlled non-randomized studies of interventions [NRSIs], 16 non-controlled NRSIs) evaluating convalescent plasma in adults with COVID-19 (total of 5443 study participants, of whom 5211 received COVID-19 convalescent plasma) found very low confidence in the efficacy and safety of this treatment approach. There was a high risk of bias within and across the studies and great variability in terms of study design, donor and recipient characteristics, and other previous or concurrent treatments. [42]

**Systematic review (Joyner et al; non-peer-reviewed):** Analysis of pooled data (total of 804 COVID-19 patient outcomes) from 12 studies (3 RCT, 5 matched-control, 4 case series) evaluating convalescent plasma in hospitalized adults with severe or life-threatening COVID-19 found evidence favoring efficacy of this therapeutic approach. The risk of death was substantially reduced in hospitalized COVID-19 patients transfused with convalescent plasma compared to matched patients receiving standard therapy (OR: 0.43, p <0.001). **Note:** There were several limitations to this analysis including aggregating mortality data

**FDA issued a guidance for industry to provide recommendations to healthcare providers and investigators regarding administration and study of investigational COVID-19 convalescent plasma.** This guidance document includes recommendations regarding pathways for access to COVID-19 convalescent plasma, collection of such plasma (including donor eligibility and qualifications), product labeling, and record-keeping. [11]

**Additional pathways (outside of the EUA) for administering or studying the use of investigational COVID-19 convalescent plasma:**

1). **Clinical Trials:** Requests to study use of COVID-19 convalescent plasma should be submitted to FDA under the traditional investigational new drug (IND) regulatory pathway. [11]

2). **Expanded Access IND:** FDA is accepting requests for expanded access INDs for use of COVID-19 convalescent plasma in patients with serious or immediately life-threatening COVID-19 who are not eligible or are unable to participate in randomized clinical trials. Consult the FDA guidance document for specific information on applying for an expanded access IND for more than a single patient. [11]

3). **Single Patient Emergency IND (eIND):** Licensed physicians seeking to administer COVID-19 convalescent plasma to individual patients with serious or life-threatening disease may request an eIND from the FDA. Consult the FDA guidance document for specific information on applying for an eIND. [11]

**Donor eligibility:** FDA guidance suggests that COVID-19 convalescent plasma be collected from individuals with laboratory-confirmed evidence of COVID-19 infection and complete resolution of symptoms for at least 14 days before donation (a negative result for COVID-19 by a diagnostic test is not necessary to qualify the donor). [11]

</table>

**Open-label, randomized, controlled study in Netherlands (Gharbharan et al; Con-COVID study):** Preliminary (non-peer-reviewed) data from a study of 86 hospitalized adults with COVID-19 found no significant difference in mortality, duration of hospital stay, or disease severity on day 15 in patients treated with convalescent plasma (300 mL of convalescent plasma containing anti-SARS-CoV-2 neutralizing antibody titers of ≥1:80 as determined by a SARS-CoV-2 plaque reduction neutralization test) compared with standard of care.

**Note:** Anti-SARS-CoV-2 antibodies were detected at baseline in 53/66 patients who had been symptomatic for 10 days prior to study enrollment. Neutralizing antibodies were detected in 44/56 (79%) patients tested with median titers comparable to the donors (1:160). These findings raised concerns about the potential benefit of convalescent plasma in the study population and the study was terminated.

**Open-label, randomized, controlled study in China (Li et al):** Results of this study in 103 adults with severe or life-threatening COVID-19 found no significant difference in time to clinical improvement within 28 days, mortality, or time to hospital discharge in patients treated with convalescent plasma (containing a high titer of antibody to SARS-CoV-2) plus standard of care compared with standard of care alone.

Convalescent plasma therapy was well tolerated by the majority of patients; 2 cases of transfusion-associated adverse events were reported. There was a signal of possible benefit in the subgroup of patients with severe COVID-19 disease. However, the study had several limitations that preclude any definite conclusions, including the possibility of being underpowered as the result of early termination because of the lack of available patients. In addition, most patients received convalescent plasma treatment at least 14 days after symptoms began.

Antibody titers in donor plasma: According to the EUA, COVID-19 convalescent plasma with an S/Co value of ≥12 (as determined by the Ortho VITROS SARS-CoV-2 IgG test) qualifies as high-titer COVID-19 convalescent plasma. Low-titer COVID-19 convalescent plasma must be labeled accordingly and may be considered for use following assessment of the potential benefits and risks of convalescent plasma therapy for the individual patient.

(non-peer-reviewed) data from a study of 58 adults hospitalized within 7 days of COVID-19 symptom onset with risk factors for disease progression and without mechanical ventilation found no significant difference in composite outcome of death, mechanical ventilation, or prolonged hospital admission (>14 days) in patients who received convalescent plasma (up to two transfusions of 200 mL) immediately following hospital admission compared with those who received convalescent plasma at clinical deterioration. Two patients developed severe respiratory deterioration within 6 hours after transfusion of convalescent plasma and were categorized as possible transfusion-associated acute lung injury (TRALI) type II. 47

**Expanded access IND protocol in US (Joyner et al):** Analysis of 35,322 adults hospitalized with laboratory-confirmed SARS-CoV-2 infection who had or were considered at high risk of progression to severe or life-threatening COVID-19 who participated in a US FDA Expanded Access Program (NCT04338360) suggests that 7- and 30-day mortality rates are substantially reduced in patients transfused with convalescent plasma within 3 days of COVID-19 diagnosis. Patients received at least one unit (approximately 200 mL) of ABO-compatible COVID-19 convalescent plasma IV according to institutional transfusion guidelines. A statistically significant difference in crude 7-day mortality was observed between patients transfused with convalescent plasma within 3 days of COVID-19 diagnosis compared with those transfused with convalescent plasma 4 or more days after COVID-19 diagnosis (8.7 vs 11.9%). Similar findings were observed for 30-day mortality rate (21.6 vs 26.7%). A reduction in 7- and 30-day mortality rate also was observed in patients transfused with convalescent plasma containing higher IgG antibody levels (>18.45 signal-to-cut-off [S/Co] ratio) compared with those transfused with convalescent plasma containing IgG antibody levels ≤18.45 S/Co. 36 Analysis of key safety indicators in 20,000 adults who participated in this Expanded Access Program.

suggests that IV transfusion of convalescent plasma is safe in hospitalized patients with COVID-19. Within the first 4 hours after transfusion, 146 serious adverse events (i.e., transfusion-associated circulatory overload, transfusion-related acute lung injury [TRALI], severe allergic transfusion reaction) were reported (incidence of <1% of all transfusions with a mortality rate of 0.3%); however, only 13/146 serious adverse events were judged by the treating clinician as related to convalescent plasma transfusion. Within 7 days after transfusion, 1136 other serious adverse events were reported (i.e., thromboembolic or thrombotic event, sustained hypotensive event requiring IV vasopressor, cardiac event); however, 55/87 thromboembolic or thrombotic complications and 569/643 cardiac events were judged to be unrelated to convalescent plasma transfusion.

**Retrospective subset analyses of Mayo Clinic expanded access protocol in US:** FDA analysis of a subset of 4330 patients indicated no difference in 7-day mortality between patients who received high-titer convalescent plasma and those who received low-titer convalescent plasma; however, subgroup analysis suggested improvement in 7-day mortality in nonintubated patients who received high-titer convalescent plasma compared with those who received low-titer convalescent plasma (11 vs 14%, respectively). Post-hoc analysis of nonintubated patients who were <80 years of age and transfused with convalescent plasma within 72 hours of COVID-19 diagnosis suggested an improvement in 7-day mortality between patients who received high-titer convalescent plasma and those who received low-titer convalescent plasma (6.3 vs 11.3%, respectively). Mayo Clinic analysis of a subset of 3082 patients indicated no difference in 30-day mortality between patients who received high-titer convalescent plasma and those who received low-titer convalescent plasma; however, similar to the FDA analysis, post-hoc subgroup analyses suggested a benefit of high-titer convalescent plasma transfused within 3 days of COVID-19 diagnosis in

<td>nonintubated patients who were &lt;80 years of age. Antibody titers for the FDA analysis were measured by the Broad Institute using a pseudovirus assay and antibody titers for the Mayo Clinic analysis were measured using the Ortho Clinical Diagnostics COVID-19 IgG assay. <strong>Open-label, prospective study (Madariaga et al):</strong> The relationship between clinical and serologic parameters in a group of COVID-19 convalescent plasma donors and antibody responses in recipients of convalescent plasma was evaluated. SARS-CoV-2 anti-receptor binding domain (anti-RBD) and anti-spike antibody titers ranged from 0 to 1:3892 and 0 to 1:3289, respectively, in 103 convalescent plasma donors; mean duration of COVID-19 symptoms in the plasma donors was 11.9 days and mean interval between symptom onset and convalescent plasma donation was 45.1 days; predictors of higher antibody titers in the donors included advanced age, fever, absence of myalgia, fatigue, ABO blood type, and previous hospitalization. In this study, 10 hospitalized adults with severe or life-threatening COVID-19 received 1 or 2 units (approximately 300 mL per unit administered IV over 4 hours) of ABO-compatible COVID-19 convalescent plasma (units had SARS-CoV-2 anti-RBD antibody titers of 1:73 to 1:3892 and anti-spike antibody titers of 1:69 to 1:2921) within 21 days after symptom onset and 80% of these patients had a significant increase in SARS-CoV-2 anti-spike and anti-RBD antibody titer by post-transfusion day 3 and were discharged after clinical improvement; antibody titers in the convalescent plasma recipients were independent of donor antibody titer. SARS-CoV-2 antibody titers in the convalescent plasma recipients continued to increase for up to 14 days in 4 recipients; however, 2 severely ill patients receiving extracorporeal membrane oxygenation (ECMO) who received convalescent plasma on day 20-21 of illness and had SARS-CoV-2 anti-spike antibody titers of up to 1:13,833 on day 0 had a decrease in antibody titer after receiving convalescent plasma. No convalescent plasma recipients</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
experienced toxicity associated with the transfusion or clinical deterioration or worsening of disease status immediately related to plasma transfusion. Convalescent plasma transfusion was safe in high-risk individuals in this study (i.e., immunosuppressed, end-stage renal disease).

**Retrospective matched cohort study** (Rogers et al; non-peer-reviewed) of hospitalized COVID-19 patients at 3 Rhode Island medical centers indicated no significant difference in in-hospital mortality or rate of hospital discharge in patients who received convalescent plasma within a median of 7 days after symptom onset; however, subgroup analysis suggested a significantly increased hospital discharge rate among convalescent plasma recipients 65 years of age or older.

**Retrospective study (Salazar et al; non-peer-reviewed)** of adults diagnosed with COVID-19 and hospitalized with pneumonia in 215 hospitals in Argentina suggested clinical benefit of convalescent plasma in such patients; a significant reduction in 28-day unadjusted mortality was observed in convalescent plasma recipients compared with those who did not receive convalescent plasma (25.5 vs 38%).

Although there is some evidence suggesting possible benefits of convalescent plasma in patients with COVID-19, available data to date are largely from case reports or series; confirmation from additional randomized controlled studies is required. Some trials are listed below. For additional trials, see clinicaltrials.gov:

Retrospective territory-wide cohort study (not peer reviewed) in Hong Kong investigating the association between famotidine use and COVID-19 severity: In this cohort of 952 adults hospitalized with COVID-19, 51 patients (5.4%) had severe disease; 23 patients (2.4%) received famotidine and 4 patients (0.4%) received proton-pump inhibitors (PPIs), as determined on the day of admission. Multivariable logistic regression analysis showed no significant association between severe COVID-19 disease and use of famotidine or PPIs.¹⁵

** Retrospective, matched, multiple-hospital study (not peer reviewed) investigating the association between in-hospital famotidine use (within 24 hours of admission) and mortality in patients with confirmed COVID-19: Famotidine users and nonusers were matched by age, gender, race and ethnicity, body mass index, comorbidities, and in-hospital hydroxychloroquine use. Patients who died or required intubation within 48 hours of admission were excluded. The post-match cohort included 410 patients (35.5%) who received famotidine and 746 matched controls (64.5%). Multivariable logistic regression analysis within the matched cohort showed no association between in-hospital famotidine use and 30-day mortality after

| HMG-CoA Reductase Inhibitors (statins) | 24:06 Antilipemic Agents | In addition to lipid-lowering effects, statins have anti-inflammatory and immunomodulatory effects, which may prevent acute lung injury. Statins affect ACE2 as part of their function in reducing endothelial dysfunction. | Data from randomized controlled trials are lacking on the use of statins in patients with COVID-19. Retrospective cohort studies in various settings have indicated potential beneficial effects of statin treatment on disease severity, mortality, and/or recovery time in patients with COVID-19. Meta-analyses conducted using data from retrospective studies have conflicting results. In a retrospective cohort study in 13,981 patients in China hospitalized with COVID-19, statin use during hospitalization was associated with lower risk of mortality. The 28-day all-cause mortality was 22% lower in patients who received statins during hospitalization compared with patients who did not receive statins. Among propensity-score-matched patients (861 patients in the statin group vs. 3444 matched patients in the no-statin group), the risk of 28-day all-cause mortality was 42% lower in patients who received statins during hospitalization compared with those who did not receive statins. In addition, lower incidence of invasive mechanical ventilation was observed in the statin-treated patients. The authors note that patients in the statin group were older and had a lower incidence of invasive mechanical ventilation. Adjustment for WHO severity rating and use of antiviral and supportive therapies. | NIH COVID-19 Treatment Guidelines Panel states patients who are receiving a statin for the treatment or prevention of cardiovascular disease should continue statin therapy. The panel recommends against use of statins for the treatment of COVID-19 except in the context of a clinical trial. Patients with cardiovascular disease are at an increased risk of serious COVID-19 infections. In patients with active COVID-19 who may develop severe rhabdomyolysis, it may be advisable to withhold statin therapy for a short period of time. Most statins are substrates for the CYP450 system; potential for drug interactions. | **Trials or Clinical Experience**

Uncontrolled series of hospitalized patients with COVID-19 receiving open-label, combined H2 and H1 antagonist therapy (famotidine and cetirizine) for ≥48 hours: Total of 110 patients at a single hospital received famotidine 20 mg and cetirizine hydrochloride 10 mg orally or IV every 12 hours; concomitant therapy included hydroxychloroquine (85%), tocilizumab (51%), methylprednisolone (31%), and convalescent plasma (30%). Findings included a 16.4% overall rate of intubation, 7.3% rate of intubation after ≥48 hours of treatment, 15.5% mortality rate, and 11-day average hospital stay. **Note:** Comparisons were limited to published outcome data from other locales for patients receiving “standard-of-care” regimens. |

</tr>
</thead>
</table>
|         |            | higher prevalence of comorbidities and more severe symptoms at baseline; matched non-statin patients therefore had more severe baseline symptoms and comorbidities than unmatched patients, which could account for the increased mortality in the non-statin group after propensity score matching.  

In a retrospective cohort study in 154 nursing home residents in Belgium with clinically suspected COVID-19 and/or positive PCR test for SARS-CoV-2, statin use was associated with absence of symptoms (i.e., asymptomatic infection) in this cohort; 45% of the 31 patients receiving statin therapy remained asymptomatic compared with 22% of the 123 patients not receiving statins.  

In a retrospective cohort study in 170 patients hospitalized for COVID-19 at a single US center, statin use prior to admission was associated with reduced risk of developing severe disease and, among those without severe disease, faster time to recovery. In this study, 27% of pts reported using statins within 30 days prior to hospitalization for COVID-19. Statin use was associated with a 71% lower risk of severe outcome (i.e., death or ICU admission). In addition, rate of recovery in patients without severe disease was higher (hazard ratio for recovery: 2.69) and median time to recovery was shorter for those who received statins. The beneficial effect of statin use on reduction of severe outcomes in patients with COVID-19 was greater than that observed in a large control cohort of COVID-19-negative patients.  

In another retrospective study of 249 patients hospitalized with COVID-19 at multiple US centers, statin use prior to hospitalization was associated with lower risk of invasive mechanical ventilation in some models, but there was no substantial association between statin use and in-hospital death or ICU admission.  

In a retrospective cohort study in 87 patients admitted to the ICU with COVID-19 |          |           |                               |         |          |
<p>| | | | | | |
|         |            |           |                               |         |          |
|         |            |           |                               |         |          |
|         |            |           |                               |         |          |
|         |            |           |                               |         |          |
|         |            |           |                               |         |          |</p>

| Immune Globulin | 80:04 Immune Globulin | Commercially available immune globulin (non-SARS-CoV-2-specific IGIV, IVIG, y-globulin): Immune globulin derived from pooled plasma containing many antibodies normally present in adult human blood; used for replacement therapy or treatment of various immune and inflammatory disorders (e.g., primary or secondary | at a single US center, treatment with atorvastatin (40 mg daily) was associated with a reduced risk of death (adjusted hazard ratio: 0.38).<ref>13</ref>

Preliminary findings from a meta-analysis (Kow & Hasan) of 4 cohort or case-control studies which included a total of 8990 patients with COVID-19 suggest that statin use is associated with a 30% reduction in risk of severe or fatal outcome in patients with COVID-19.<ref>14</ref> However, another meta-analysis of 9 cohort or case-control studies (Hariyanto & Kurniawan) did not find an association between statin use and improved severity or mortality outcomes in patients with COVID-19. This meta-analysis included a total of 3449 pts with COVID-19 and included 2 of the same studies used in the Kow & Hasan analysis.<ref>15</ref>

Preliminary findings have shown mixed results with other respiratory illnesses; some observational studies suggest statin therapy is associated with a reduction in various cardiovascular outcomes and possibly mortality in patients hospitalized with influenza and/or pneumonia.<ref>3-6</ref>

**Clinical trials evaluating statin use in COVID-19:** Multiple trials registered at clinicaltrials.gov (some listed below):<ref>9</ref>
NCT04333407
NCT04343001
NCT04348695
NCT04426084
NCT0440727 (STACOV)

Commercially available immune globulin (non-SARS-CoV-2-specific IGIV) and investigational anti-SARS-CoV-2 hyperimmune globulin (anti-SARS-CoV-2 hIGIV) in the treatment of COVID-19 is unclear.<ref>16</ref>

The NIH COVID-19 Treatment Guidelines Panel recommends against the use of commercially available IGIV (non-SARS-CoV-2-specific IGIV) for the treatment of COVID-19 except in the context of a clinical trial and states that current...

<td>In vitro evidence of activity against SARS-CoV-2 in infected Vero-hSLAM cells reported with high concentrations of the drug 7</td>
<td>Pilot observational study comparing efficacy of add-on ivermectin in pts with mild to moderate COVID-19 (not peer reviewed): A total of 16 pts received a single dose of oral ivermectin (0.2 mg/kg) given on the day of hospital admission in addition to initiation of treatment with hydroxychloroquine and azithromycin, and results were compared with 71 pts who received hydroxychloroquine and azithromycin alone (matched controls). The primary outcome was percentage of pts cured (defined as symptoms free to be discharged from the hospital and 2 consecutive negative PCR tests from nasopharyngeal swabs at least 24 hours apart) within 23 days. The investigators reported that all 16 pts who received ivermectin were cured compared with 97% of pts who did not receive ivermectin and the mean duration of hospitalization was shorter in the ivermectin group (7.6 days) than in the control group (13.2 days). Note: These results need to be validated in a larger prospective trial.</td>
<td></td>

<tr>
<td></td>
<td></td>
<td>Retrospective observational evaluation of COVID-19 pts treated with ivermectin (not peer reviewed): Outcome data for 173 pts with confirmed COVID-19 who received at least one dose of oral ivermectin (0.2 mg/kg) at any time during hospitalization, at the discretion of the treating physician, in addition to usual care were compared with outcome data for 107 pts who received usual care. The primary outcome measure was all-cause in-hospital mortality. The investigators reported that overall mortality was lower in the ivermectin group (15%) than in the group not treated with ivermectin (25.2%); there was no difference in duration of hospitalization between the groups (median of 7 days for both groups). Note: The effect of ivermectin on viral load was not evaluated and the impact of confounding factors in these patients (e.g., time from diagnosis to initiation of treatment, differences in drugs used for standard care and variances in clinical benefits of such drugs) is not known.</td>

No published data to date from randomized, controlled clinical trials to support use in the treatment or prevention of COVID-19

NIH COVID-19 Treatment Guidelines Panel **recommends against** use of ivermectin for the treatment of COVID-19, except in a clinical trial 13

Ivermectin plasma concentrations attained with dosages recommended for treatment of parasitic infections are substantially lower than concentrations associated with in vitro inhibition of SARS-CoV-2; 7,9 pharmacokinetic modeling predicts that plasma concentrations attained with dosages up to 10 times higher than usual dosage also are substantially lower than concentrations associated with in vitro inhibition of the virus 9

FDA issued a warning concerning possible inappropriate use of ivermectin products intended for animals as an attempt to self-medicate for the treatment of COVID-19 8

<td>Nebulized drugs</td>
<td></td>
<td>Potential harm: Concern that use of nebulized drugs (e.g., albuterol) for the management of respiratory conditions in patients with COVID-19 infection may distribute the virus into the air and expose close contacts.(^1,2,4,5)</td>
<td>Various clinical trials evaluating ivermectin for the treatment or prevention of COVID-19 are registered at clinicaltrials.gov(^10)</td>
<td></td>
<td>American College of Allergy, Asthma &amp; Immunology (ACAAI) recommends that nebulized albuterol should be administered in a location that minimizes exposure to close contacts who do not have COVID-19 infection. In the home, choose a location where air is not recirculated (e.g., porch, patio, or garage) or areas where surfaces can be cleaned easily or may not need cleaning.(^1,4) In hospitals, clinicians typically use nebulizers to deliver medications such as albuterol, but are being encouraged to switch to use of metered-dose or dry powder inhalers in patients who are awake and who can perform specific breathing techniques because of the risk of the virus becoming airborne when treating patients infected with COVID-19.(^2,5) There is a lack of published information and guidance on the optimal administration of aerosolized drugs in the treatment of patients with COVID-19. The safe and effective delivery of aerosol therapy to such patients may require modifications in dosage, frequency, and delivery techniques.(^5) WHO states there is insufficient evidence to classify nebulizer therapy as an aerosol-generating procedure associated with COVID-19 transmission and that further study is needed.(^6)</td>

<tr>
<td>Nonsteroidal Anti-inflammatory Agents (NSAIAs)</td>
<td>28:08.04</td>
<td>Speculative link between ibuprofen and increased ACE2 expression, which possibly could lead to worse outcomes in COVID-19</td>
<td>Multiple other clinical trials planned or initiated to evaluate nitazoxanide in combination with other drugs [e.g., hydroxychloroquine, ivermectin] or alone for treatment of COVID-19</td>
<td>4 times daily, 1600 mg 3 times daily, and 2900 mg twice daily in the fasted state and 700 mg 4 times daily, 900 mg 3 times daily, and 1400 mg twice daily in the fed state are capable of maintaining plasma and lung tizoxanide (major metabolite of nitazoxanide) exposures exceeding the EC50 for SARS-CoV-2.</td>
<td>Concerns that anti-inflammatory drugs such as ibuprofen may worsen COVID-19 circulated widely in the early months of the pandemic. These reports were based largely on a letter published in The Lancet Respir Med stating that increased expression of ACE2 could facilitate infection with COVID-19 and that ibuprofen can increase ACE2. In addition, there were unconfirmed reports of younger, healthy patients who had used ibuprofen to treat early symptoms of COVID-19 and later experienced severe outcomes. A statement attributed to the WHO recommending paracetamol and avoiding ibuprofen as a self-medication was widely circulated in the media; however, such a position by the WHO has not been substantiated. WHO subsequently performed a rapid review of the literature and concluded that there was no evidence at that time of severe adverse events or effects on acute health care utilization, long-term survival, or quality of life in patients with COVID-19 as a result of the use of NSAIAs. FDA has stated that it is not aware of scientific evidence connecting the use of NSAIAs, such as ibuprofen, with worsening COVID-19 symptoms and will communicate publicly when more information is available. FDA also noted that all prescription NSAIA labels warn that these drugs may diminish the utility of diagnostic signs in detecting infections. Although there currently is no compelling evidence to support an association.</td>

<td>Thrombolytic Agents (t-PA [alteplase], tenecteplase)</td>
<td>Updated 10/1/20</td>
<td>A consistent finding in patients with severe COVID-19 is a hypercoagulable state, which has been shown to contribute to poor outcomes (e.g., progressive respiratory failure, acute respiratory distress syndrome [ARDS], death).</td>
<td>Results of a small phase 1 study suggested possible benefit of plasminogen activators in the treatment of ARDS. In this study, 20 patients with ARDS secondary to trauma and/or sepsis who failed to respond to standard ventilator therapy and were not expected to survive were treated with urokinase or streptokinase; such therapy improved PaO&lt;sub&gt;2&lt;/sub&gt; and also appeared to improve survival. In a case series of 5 COVID-19 patients who had severe hypoxemia, declining respiratory status, and increasing oxygen requirements, administration of t-PA (alteplase) at an initial IV bolus dose of 25 mg over 2 hours followed by a continuous IV infusion of 25 mg over the next 22 hours appeared to improve oxygen requirements in all patients and prevent progression to mechanical ventilation in 3 of the patients.</td>
<td>t-PA (alteplase): Dosage regimens being evaluated in the registered NCT04357730 trial: 50 mg (administered as a 10-mg IV bolus followed by IV infusion of the remaining 40 mg over a total time of 2 hours) and 100 mg (administered as a 10-mg IV bolus followed by IV infusion of the remaining 90 mg over a total time of 2 hours); both regimens will be followed by a heparin infusion immediately after completion of the alteplase infusion. Other t-PA (alteplase) dosage regimens evaluated in patients with COVID-19 include an initial t-PA (alteplase) dose of 25 mg administered IV over 2 hours, followed by an IV infusion of 25 mg over the next 22 hours.</td>
<td>t-PA has been proposed as a salvage treatment for COVID-19 patients (e.g., those with decompensating respiratory function who are not responding to or do not have access to mechanical ventilation or extracorporeal membrane oxygenation [ECMO]). Preliminary findings from the first few cases reported an initial, but transient improvement in PaO&lt;sub&gt;2&lt;/sub&gt;/FiO&lt;sub&gt;2&lt;/sub&gt; (P/F) ratio. The NIH COVID-19 Treatment Guidelines Panel states that current data are insufficient to recommend for or against the use of thrombolytic agents in between ibuprofen and negative outcomes in patients with COVID-19, some experts have recommended preferentially using acetaminophen for treatment of fever. NIH COVID-19 Treatment Guidelines Panel states that patients who are receiving NSAIDs for other conditions should continue receiving the drugs; the panel also states that antipyretic strategy (e.g., use of acetaminophen or NSAIDs) should be no different between patients with or without COVID-19. The Surviving Sepsis Campaign COVID-19 guidelines state that until more evidence is available, use of acetaminophen over no treatment for fever control is suggested (weak recommendation). IDSA makes no specific recommendation for or against the use of NSAIDs in patients with COVID-19. Indomethacin: Additional data needed to determine whether in vitro activity against SARS-CoV-2 corresponds with clinical efficacy in the treatment of COVID-19.</td>

<tr>
<td>A consistent finding in patients with ARDS (regardless of the cause) is fibrin deposition and microthrombi formation in the alveoli and pulmonary vasculature. 1, 11, 14 Dysregulation of the clotting system in ARDS is a result of both enhanced activation of coagulation and suppression of fibrinolysis. 12, 19 Fibrinolysis shutdown, as evidenced by complete failure of clot lysis on thromboelastography, has been observed in critically ill patients with COVID-19. 1, 23 Thrombolytic therapy may restore microvascular patency and limit progression of ARDS in patients with COVID-19 1, 14, 19, 22</td>
<td>Other case series have described the use of t-PA in COVID-19 patients with severe respiratory failure or ARDS who were rapidly deteriorating and were either already on mechanical ventilation or likely to require intubation. Following IV infusion of t-PA (dosages varied), the majority of patients responded with rapid improvement in oxygenation. 21, 24 However, multiple confounding factors limit interpretation of findings from these case reports. 21, 24</td>
<td>subsequent 22 hours, with a dose not to exceed 0.9 mg/kg; however, the optimum dose, route of administration, and duration of treatment remain to be determined. 1, 9, 14, 20 Tenecteplase: A low-dose IV bolus of tenecteplase (0.25 mg/kg or 0.5 mg/kg) is being evaluated in the registered NCT04505592 trial. 1</td>
<td>hospitalized COVID-19 patients outside the setting of a clinical trial; patients who develop catheter thrombosis or other indications for thrombolytic therapy should be treated according to the usual standard of care in patients without COVID-19. 17 The CHEST guideline for the prevention, diagnosis, and treatment of VTE in patients with COVID-19 states that there is a lack of evidence regarding use of thrombolytic therapies in critically ill patients with COVID-19 without objective evidence of VTE or VTE-associated hypotension; based on indirect evidence from other populations, the expert panel recommends against the use of thrombolytic therapy in COVID-19 patients without objectively confirmed PE and PE-induced hypotension. 25 The Anticoagulation Forum recommends against the use of thrombolytic agents in COVID-19 patients outside the setting of a clinical trial unless there is another clinical indication (e.g., STEMI, acute ischemic stroke, high-risk [massive] PE with hemodynamic compromise); in general, thrombolytic therapy is not recommended in the vast majority of patients with PE given limited efficacy data in patients who are hemodynamically stable. 26 The American Society of Hematology states that treatment of the underlying pathology is paramount in COVID-19 patients with coagulopathies; supportive care should be individualized and standard risk factors for bleeding should be considered. 28</td>
