# Assessment of Evidence for COVID-19-Related Treatments: Updated 04/30/2021

The information contained in this evidence table is emerging and rapidly evolving because of ongoing research and is subject to the professional judgment and interpretation of the practitioner due to the uniqueness of each medical facility’s approach to the care of patients with COVID-19 and the needs of individual patients. ASHP provides this evidence table to help practitioners better understand current approaches related to treatment and care. ASHP has made reasonable efforts to ensure the accuracy and appropriateness of the information presented. However, any reader of this information is advised ASHP is not responsible for the continued currency of the information, for any errors or omissions, and/or for any consequences arising from the use of the information in the evidence table in any and all practice settings. Any reader of this document is cautioned that ASHP makes no representation, guarantee, or warranty, express or implied, as to the accuracy and appropriateness of the information contained in this evidence table and will bear no responsibility or liability for the results or consequences of its use.

Selected entries were updated 04/30/2021; these can be identified by the date that appears in the Drug(s) column. Within updated entries, select revisions that include the most important new information (e.g., new clinical trial data, new or revised guidance) are marked by **.

## TABLE OF CONTENTS

### ANTIVIRAL AGENTS
- BALOXAVIR
- CHLOROQUINE PHOSPHATE
- FAVIPIRAVID (Avigan®, Avifavir®, Favilavir)
- HIV PROTEASE INHIBITORS (e.g., LPV/RTV, Kaletra®)
- HYDROXYCHLOROQUINE (Plaquenil®)
- NEURAMINIDASE INHIBITORS (e.g., oseltamivir)
- REMDESVIR (Veklury®)
- SARS-CoV-2-SPECIFIC MONOCLONAL ANTIBODIES
- UMIFENOVIR (Arbidol®)

### SUPPORTING AGENTS
- ANAKINRA (Kineret®)
- ASCORBIC ACID
- AZITHROMYCIN
- BARICITINIB (Olumiant®)
- COLCHICINE
- CORTICOSTEROIDS (systemic)
- CORTICOSTEROIDS (inhaled)
- INHALED PROSTACYCLINS
- INTERFERONS
- NITRIC OXIDE (inhaled)
- RUXOLITINIB (Jakafi®)
- SARILUMAB (Kevzara®)
- SILTUXIMAB (Sylvent®)
- SIROLIMUS (Rapamune®)
- TOCILOLUMAB (Actemra®)
- VITAMIN D
- ZINC

### OTHER
- ACE INHIBITORS, ANGIOTENSIN II RECEPTOR BLOCKERS (ARBs)
- ANTICOAGULANTS
- COVID-19 CONVALESCENT PLASMA
- FAMOTIDINE
- FLUVOXAMINE (Luvox CR®)
- HMG-CoA REDUCTASE INHIBITORS (statins)
- IMMUNE GLOBULIN
- IVERMECTIN
- NEBULIZED DRUGS
- NICLOSAMIDE
- NITAZOXANIDE (Alinia®)
- NONSTEROIDAL ANTI-INFLAMMATORY AGENTS (NSAIDs)
- THROMBOLYTIC AGENTS (t-PA alteplase, tenecteplase)
## ANTIVIRAL AGENTS

<td>Baloxavir</td>
<td>8:18.92</td>
<td><strong>Antiviral active against influenza viruses</strong></td>
<td>Only very limited data available regarding use of baloxavir for treatment of COVID-19. Exploratory, open-label, randomized controlled study at a single center in China (ChicTR2000029544): 29 adults hospitalized with COVID-19 receiving antiviral treatment with lopinavir/ritonavir, darunavir/cockistat, or umifenovir (Arbidol®), in combination with inhaled interferon-α, were randomized to treatment with baloxavir marboxil (80 mg orally on day 1 and on day 4, and 80 mg orally on day 7 as needed) (n=10), favipiravir (1600 or 2200 mg orally on day 1, followed by 600 mg three times daily for up to 14 days) (n=9), or control (standard antiviral treatment) (n=10). Results did not indicate a benefit of adding baloxavir to the treatment regimen. Percentage of pts with viral conversion (2 consecutive tests with undetectable viral RNA results) after 14 days of treatment was 70%, 77%, and 100% in the baloxavir, favipiravir, and control groups, respectively, with median time to clinical improvement of 14, 14, and 15 days, respectively. ¹ ² There are no clinical trials registered at clinicaltrials.gov to evaluate baloxavir for treatment of COVID-19.</td>
<td>A baloxavir marboxil dosage of 80 mg on day 1 and on day 4, and another dose of 80 mg on day 7 (as needed; not to exceed 3 total doses) was used in one open-label COVID-19 study in adults in China. ³</td>
<td>Although investigated as a potential treatment during the early stages of the COVID-19 pandemic, ¹ ² ³ ⁴ ⁵ in vitro antiviral activity against SARS-CoV-2 was not confirmed and there are no data to support the use of baloxavir in the treatment of COVID-19. ⁶ ⁷ NIH COVID-19 Treatment Guidelines Panel states that treatment of influenza is the same in all pts regardless of SARS-CoV-2 coinfection. ⁸ (See Neuraminidase Inhibitors in this Evidence Table.) Significant drug interactions not expected with baloxavir and remdesivir. ⁹ CDC states that baloxavir may be used for the treatment of suspected or confirmed uncomplicated influenza in outpatient; the drug is not recommended for use in pregnant or nursing women, as monotherapy in severely immunosuppressed pts, or for the treatment of severe influenza. ⁴ ⁵ ⁶ ⁷</td>
</tr>
<tr>
<td>Chloroquine Phosphate</td>
<td>8:30.08</td>
<td><strong>In vitro activity against various viruses, including coronaviruses</strong> ¹ ³ ¹³ ¹⁴</td>
<td>Only limited clinical trial data available to date to evaluate use of chloroquine for treatment or prevention of COVID-19. In vitro activity against SARS-CoV-2 in infected Vero E6 cells reported; some evidence it may block infection in Vero E6 cells exposed to SARS-CoV-2 ¹ ⁴ ¹² Active in vitro against SARS-CoV-1 and MERS-CoV ² ³ ⁵ ⁹ Has immunomodulatory activity that theoretically could contribute to an anti-inflammatory response in inflammatory response in SARS-CoV-2 ¹ ² ⁴ ¹³ ¹⁴</td>
<td>Consider: 500 mg of chloroquine phosphate is equivalent to 300 mg of chloroquine base ¹⁷ Oral chloroquine phosphate dosage suggested in the EUA (now revoked): For treatment of hospitalized adults and adolescents weighing 50 kg or more, suggested dosage was 1 g on day 1, then 500 mg daily for 4–7 days of total treatment based on clinical evaluation. ²⁵ FDA now states that this dosage regimen is unlikely to have an antiviral effect in pts with COVID-19 based on a reassessment of in vitro EC&lt;sub&gt;50&lt;/sub&gt;/EC&lt;sub&gt;90&lt;/sub&gt; data and calculated lung concentrations; it is unclear whether this dosage regimen would provide any beneficial immunomodulatory effects. ²⁷</td>
<td>Efficacy and safety of chloroquine for treatment or prevention of COVID-19 not established ¹⁰ ²⁴ ³⁹ No data to date indicating that in vitro activity against SARS-CoV-2 corresponds with clinical efficacy for treatment or prevention of COVID-19 ⁸ ⁹ Data from various published randomized, controlled clinical trials and retrospective, cohort studies have not substantiated initial reports of efficacy of 4-aminoquinoline antimalarials for treatment of COVID-19. (See Hydroxychloroquine in this Evidence Table.) NIH COVID-19 Treatment Guidelines Panel recommends against use of chloroquine for treatment of COVID-19. ¹⁰ ²⁴ ³⁹ ⁸ ⁹ ⁴ ⁵ ⁶ ⁷ ⁸ ⁹ ¹⁰ ²⁴ ³⁹</td>

<td>patients with viral infections 1-3, 13, 15-16</td>
<td>Known pharmacokinetics and toxicity profile based on use for other indications 13, 17</td>
<td>the hospital by day 14. <strong>Note:</strong> Results suggest that chloroquine was associated with shorter time to RT-PCR conversion and quicker recovery than LPV/RTV; however, this study included a limited number of pts and the median time from onset of symptoms to initiation of treatment was shorter in those treated with chloroquine than in those treated with LPV/RTV (2.5 vs 6.5 days, respectively). 20</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td><strong>Double-blind, randomized, phase 2b study in Brazil (Borba et al; NCT04323527):</strong> Efficacy and safety of two different chloroquine dosages were evaluated for adjunctive therapy in hospitalized adults with severe COVID-19. According to the initial study protocol, pts were randomized 1:1 to receive high-dose chloroquine (600 mg twice daily for 10 days) or lower-dose chloroquine (450 mg twice daily on day 1, then 450 mg once daily on days 2-5); all pts also received azithromycin and ceftriaxone and some also received oseltamivir. An unplanned interim analysis was performed and the high-dose arm of the study was halted because of toxicity concerns, particularly QTc prolongation and ventricular tachycardia, and because more deaths were reported in this arm. Analysis of data available for the first 81 enrolled pts indicated that, by day 13, 16/41 pts (39%) treated with the high-dose regimen had died vs 6/40 (15%) treated with the lower-dose regimen. QTc &gt;500 msec occurred more frequently in the high-dose group (18.9%) than in the lower-dose group (11.1%). <strong>Note:</strong> The high-dose arm included more pts prone to cardiac complications than the lower-dose arm. Data at the time of the interim analysis were insufficient to evaluate efficacy. 37</td>

should be used concomitantly with drugs that pose a moderate to high risk for QT prolongation (e.g., antiarrhythmics, antipsychotics, antifungals, fluoroquinolones, macrolides [including azithromycin]) only if necessary. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving chloroquine (or hydroxychloroquine). 25

FDA issued a safety alert regarding adverse cardiac effects (e.g., prolonged QT interval, ventricular tachycardia, ventricular fibrillation) reported with use of chloroquine or hydroxychloroquine (either alone or in conjunction with azithromycin or other drugs known to prolong QT interval) in hospital and outpatient settings; **FDA cautions against** use of chloroquine or hydroxychloroquine outside of a clinical trial or hospital setting and urges healthcare professionals and pts to report adverse effects involving these drugs to **FDA MedWatch**. 39

**Emergency use authorization (EUA) for chloroquine (now revoked):** Effective June 15, 2020, FDA has revoked the EUA for chloroquine and hydroxychloroquine previously issued on March 28, 2020 that permitted distribution of the drugs from the strategic national stockpile (SNS) for use in adults and adolescents weighing 50 kg or more hospitalized with COVID-19 for whom a clinical trial was not available or participation not feasible. 24, 57 Based on a review of new information and reevaluation of information available at the time the EUA was issued, FDA concluded that the original criteria for issuance of the EUA for these drugs are no longer met. 57 Based on the totality of scientific evidence available, FDA concluded that it is unlikely that chloroquine and hydroxychloroquine may be effective in treating COVID-19 and, in light of ongoing reports of serious cardiac adverse events and several newly reported cases of methemoglobinemia in COVID-19...

<tr>
<td>Favipiravir</td>
<td>8:18.32</td>
<td>Antiviral</td>
<td>Some data regarding use of favipiravir for the treatment of COVID-19 are available from open-label, randomized or nonrandomized studies and prospective or retrospective observational studies performed in various countries. In vitro evidence of activity against SARS-CoV-2 in infected Vero E6 cells reported with high concentrations of the drug. In Japan and China for treatment of influenza.</td>
<td>A favipiravir dosage of 1600 mg twice daily on day 1, then 600 mg twice daily thereafter for 7–10 or 14 days was used in several open-label COVID-19 studies in adults and adolescents ≥16 years of age in other countries. Protocols in many registered trials generally specify a favipiravir dosage of 1600 or 1800 mg twice daily on day 1, then a total daily dosage of 1200–2000 mg in 2, 3, or 4 divided doses for 4–13 days for treatment of COVID-19 in adults. Protocol in one trial specifies a prophylactic favipiravir dosage of 1600 mg twice daily on day 1, then 800 mg twice daily on days 2–25 and a treatment favipiravir dosage of 2000 mg twice daily on day 1, then 1000 mg twice daily on days 2–14 in older adults in long-term care homes experiencing COVID-19 outbreaks. The prophylactic regimen is considered pre-exposure prophylaxis, or preemptive therapy in this setting; those diagnosed with COVID-19 will be offered the treatment regimen. Because high favipiravir concentrations are required for in vitro activity against SARS-CoV-2, it has been suggested that high favipiravir dosages, like those used in the treatment of Ebola virus disease, should be considered for the treatment of COVID-19. One such favipiravir regimen used in the treatment of Ebola virus disease includes a loading dosage of 6000 mg (doses of 2400 mg, 2400 mg, and 1200 mg given 8 hours apart on day 1), then a maintenance dosage of 1200 mg every 12 hours on days 2–10. Not commercially available in the US.</td>
<td>patients, the known and potential benefits of chloroquine and hydroxychloroquine do not outweigh the known and potential risks associated with the use authorized by the EUA. (See Hydroxychloroquine in this Evidence Table.) Efficacy and safety of favipiravir for treatment of COVID-19 not established. Additional data needed to substantiate initial reports of efficacy for treatment of COVID-19 and identify optimal dosage and treatment duration. Given the lack of pharmacokinetic and safety data for the high favipiravir dosages proposed for treatment of COVID-19, the drug should be used with caution at such dosages. There is conflicting evidence as to whether favipiravir is associated with QT prolongation. Some have suggested close cardiac and hepatic monitoring during treatment, as well as monitoring of plasma and tissue concentrations of the drug and, if possible, the active metabolite. Some data suggest that favipiravir exposure may be greater in Asian populations. Early embryonic deaths and teratogenicity observed in animal studies. Favipiravir is contraindicated in women with known or suspected pregnancy and precautions should be taken to avoid pregnancy during treatment with the drug. Based on a pharmacokinetic interaction, if favipiravir is used in pts receiving acetaminophen, the maximum recommended daily dosage of acetaminophen is 3 g. Note that favipiravir-induced fever has been described in several COVID-19 pts receiving the drug.</td>

<tr>
<td>Open-label, prospective, randomized, multicenter study in patients hospitalized with asymptomatic or mild COVID-19 in Japan (jRCTs041190120): Early treatment (beginning on day of hospital admission) with favipiravir (two 1800-mg doses given orally at least 4 hours apart on day 1, then 800 mg orally twice daily for a total of up to 19 doses over 10 days) (n=36) was not associated with significant improvement in viral clearance compared with late treatment with favipiravir (same regimen beginning day 6 after admission) (n=33). Viral clearance occurred by day 6 in 66.7 and 56.1% of patients in the early and late treatment groups, respectively. Viral clearance was assessed by RT-PCR of nasopharyngeal specimens. Most common adverse effect was transient hyperuricemia (84.1% of patients). 29</td>

</table>

In an open-label, randomized controlled trial in Oman in 89 adults (≤75 years of age) hospitalized with moderate to severe COVID-19 pneumonia (NCT04385095), pts received favipiravir (1600 mg on day 1, then 600 mg twice daily for a maximum of 10 days) in combination with inhaled interferon β-1b (n=44) or standard of care (which included hydroxychloroquine) (n=45). At interim analysis, there were no differences between the groups in improvement in inflammatory markers or other clinical outcomes (e.g., hospital length of stay, hospital discharge, 14-day mortality); however, the study lacked sufficient power to detect such differences. 43

**In an open-label, randomized controlled trial in India in 150 adults with asymptomatic, mild, or moderate COVID-19, pts received favipiravir (1800 mg twice daily on day 1, then 800 mg twice daily for up to 14 days total) plus standard care (n=75) or standard care alone (n=75). The median time to cessation of oral viral shedding of SARS-CoV-2 (primary end point) was 5 days in the favipiravir group compared with 7 days in the control group; this was numerically lower but not statistically significant. The median time to clinical cure among pts who were symptomatic at baseline was significantly faster in the favipiravir group (3 days) compared with the control group**

For the treatment of COVID-19, one pharmacokinetic simulation model suggested that a dosage of 2400 mg twice daily on day 1, followed by 1600 mg twice daily on days 2–10 should achieve adequate favipiravir trough plasma concentrations and may be more pharmacologically relevant than lower dosages. 35

Another pharmacokinetic simulation model suggested that, despite rapid clearance of the parent drug from plasma, a favipiravir dosage of 1600 mg twice daily on day 1 followed by maintenance doses of 800 or 1200 mg twice daily may be sufficient to provide therapeutic intracellular concentrations of the favipiravir metabolite across the dosing interval, owing to its long intracellular half life. 46

Pharmacokinetic data are available from a study in critically ill pts with COVID-19 requiring mechanical ventilation who received a favipiravir dosage of 1600 mg twice daily on day 1, then 600 mg twice daily on days 2–5 (or longer if needed) via NG tube. Trough serum concentrations of the drug in most samples were lower than the lower limit of quantification and lower than the in vitro EC50 of the drug reported for SARS-CoV-2; trough concentrations in these critically ill pts also were much lower than those previously reported in healthy individuals who received the same dosage. 52

While its molecular weight, protein binding rate, and volume of distribution suggest that favipiravir would be eliminated by dialysis, data from a COVID-19 pt treated with favipiravir (1800 mg twice daily on day 1, then 800 mg twice daily) who was undergoing hemodialysis (2 or 3 times weekly) indicated that blood concentrations of the drug were similar to those reported in nondialysis pts. 35

<td>In a retrospective, observational, multicenter study in 63 adults with COVID-19 in Thailand who received favipiravir (median loading dose of 47.4 mg/kg on day 1 and median maintenance doses of 17.9 mg/kg per day for a median total duration of 12 days), clinical improvement at day 7 was reported in 66.7% of patients (92.5% in patients not requiring oxygen supplementation, 47.2% in patients requiring oxygen supplementation) and clinical improvement at day 14 was reported in 89.7% of patients (100% in patients not requiring oxygen supplementation, 75% in patients requiring</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
oxygen supplementation). Overall mortality at day 28 was 4.8%. Nearly all patients also received a chloroquine-based therapy and an HIV protease inhibitor. Multivariate analysis revealed that older age, higher baseline disease severity, and loading doses <45 mg/kg per day were negative predictors of early clinical improvement.  

In a retrospective cohort study of 26 pts with COVID-19 who received various antiviral regimens in Japan, 3 pts ≥74 years of age received treatment that included favipiravir; 2 of these pts demonstrated improvement and 1 pt died.  

In a meta-analysis of 13 studies assessing the efficacy and safety of favipiravir in the treatment of COVID-19, clinical deterioration was less likely with favipiravir than with other antiviral agents, although the difference was not statistically significant, and those treated with favipiravir had substantial clinical and radiological improvements compared with those treated with standard of care. Viral clearance, requirement for oxygen or noninvasive ventilation, and adverse effects were similar between the favipiravir and standard of care treatment groups.  

Multiple clinical trials initiated in pts with COVID-19 in the US, China, Japan, and other countries to evaluate favipiravir alone or in conjunction with other antivirals or other agents.

<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

<sup>a</sup> Results for SARS-CoV-2 by day 13 and were discharged from the hospital by day 14; 11/12 pts (92%) treated with LPV/RTV were negative for SARS-CoV-2 at day 14 and only 6/12 (50%) were discharged from the hospital by day 14. Note: Results suggest that chloroquine was associated with shorter time to RT-PCR conversion and quicker recovery than LPV/RTV; however, this study included a limited number of pts and the median time from onset of symptoms to initiation of treatment was shorter in those treated with chloroquine than in those treated with LPV/RTV (2.5 vs 6.5 days, respectively)."

Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. From March 22 to July 4, 2020, 1411 pts were randomized to receive LPV/RTV (two tablets containing LPV 200 mg/RTV 50 mg orally twice daily for 14 days) with local standard of care and 1380 pts were randomized to LPV/RTV control (i.e., local standard of care only). Clinical characteristics at baseline were well balanced between groups. Data analysis for the intention-to-treat (ITT) population (1399 pts in LPV/RTV group and 1372 pts in standard of care group) indicated that LPV/RTV did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for LPV/RTV in the ITT population was 1.00: 148/1399 pts treated with LPV/RTV (9.7%) and 146/1372 pts treated with standard of care (10.3%) died. Ventilation was initiated after randomization in 126 pts receiving LPV/RTV and 121 pts receiving standard of care. |

(54.8%) in control group. Total of 4 pts progressed to severe illness (all in the control group). 31 Note: This study did not include pts with severe disease and pts received other anti-infectives in addition to hydroxychloroquine. At study entry, 9 pts without fever and 9 pts without cough were included in hydroxychloroquine group and 14 pts without fever and 16 pts without cough were included in control group; unclear how these pts were addressed in TTCR calculations. Although initial registered study protocol specified 2 different hydroxychloroquine treatment groups and a placebo group (each with 100 pts) and primary end points of time to negative nucleic acid and T-cell recovery, 32 data provided only for certain clinical symptoms in 62 pts without severe disease and PCR results not reported. 31

Hydroxychloroquine randomized, parallel-group, open-label study in hospitalized adults with mild to moderate COVID-19 in China (ChiCTR2000029868): 150 pts (148 with mild to moderate disease and 2 with severe disease) were randomized 1:1 to receive hydroxychloroquine (1200 mg daily for 3 days, then 800 mg daily for total treatment duration of 2-3 weeks) with standard of care or standard of care alone. Mean time from onset of symptoms to randomization was 16.6 days (range: 3-41 days). Standard of care included IV fluids, O₂, various antivirals (e.g., umifenovir, LPV/RTV), antibiotics, and/or glucocorticoid therapy. By day 28, 73% of pts (53 treated with hydroxychloroquine with standard of care and 56 treated with standard of care alone) had converted to negative for SARS-CoV-2. The probability of negative conversion by day 28 in those treated with hydroxychloroquine was similar to that in those treated with standard of care alone; the median time to negative seroconversion (6 and 7 days) also was similar in both groups. Adverse effects reported in 30% of those treated with hydroxychloroquine and 9% of those treated with standard of care alone. Note: Results indicate that use of hydroxychloroquine in pts with mild to moderate COVID-19 did not provide additional benefits compared with use of standard of care alone. 49

NII COVID-19 Treatment Guidelines Panel recommends against the use of hydroxychloroquine for postexposure prophylaxis (PEP) for prevention of SARS-CoV-2 infection and also recommends against the use of other drugs for PEP, except in a clinical trial. 35 The panel states that, to date, no agent is known to be effective for preventing SARS-CoV-2 infection when given after an exposure. In addition, results of several randomized, controlled trials evaluating hydroxychloroquine for PEP (see Trials or Clinical Experience) indicated the drug was not effective and increased the risk of adverse events compared with placebo. 35

Because 4-aminooquinolines (hydroxychloroquine, chloroquine) and azithromycin are independently associated with QT prolongation and because concomitant use of the drugs may further increase the risk of QT prolongation, caution is advised if considering use of hydroxychloroquine (with or without azithromycin) in pts with COVID-19, especially in outpatients who may not receive close monitoring and in those at risk for QT prolongation or receiving other drugs associated with arrhythmias. 35, 36, 38, 39, 41-44

NIH panel states that 4-aminooquinolines (hydroxychloroquine, chloroquine) should be used concomitantly with drugs that pose a moderate to high risk for QT prolongation (e.g., antiarrhythmics, antipsychotics, antifungals, fluoroquinolones, macrolides [including azithromycin]) only if necessary. In addition, because of the long half-lives of both hydroxychloroquine (up to 40 days) and azithromycin (up to 72 hours), caution is warranted even when these drugs are used sequentially. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving hydroxychloroquine (or chloroquine). 35

<td>Hydroxychloroquine with azithromycin</td>
<td></td>
<td></td>
<td>uncontrolled, retrospective, observational study in France (Gautret et al): 80 adults with confirmed COVID-19 (including 6 pts included in a previous study by the same group) were treated with hydroxychloroquine sulfate (200 mg 3 times daily for 10 days) and azithromycin (500 mg on day 1, then 250 mg daily on days 2-5). Majority (92%) were considered low risk for clinical deterioration (low national early warning score for COVID-19 based on age, respiratory rate, $O_2$ saturation, temperature, BP, pulse, level of consciousness); only 15% had fever; 4 pts were asymptomatic carriers; mean time from onset of symptoms to treatment initiation was 4.9 days. Clinical outcome, contagiousness as assessed by nasopharyngeal PCR assay and culture, and length of stay in infectious disease (ID) unit were evaluated in pts who were treated for at least 3 days and followed for at least 6 days. Favorable outcome was reported for 81.3%; 15% required $O_2$; 3 pts transferred to ICU; 1 pt died; mean time to discharge from ID unit was 4.1 days. At day 8, PCR results were negative in 93% of those tested; at day 5, viral cultures were negative in 97.5% of those tested. <strong>Note:</strong> Almost all pts were considered low risk for clinical deterioration (including 4 pts described as asymptomatic carriers) and it is unclear how many would have had spontaneous conversion to negative nasopharyngeal samples during same time frame. Although 80 pts were enrolled, PCR results available for fewer pts beginning on day 3 and only 60 pts represented in day 6 data. This was an uncontrolled study and data presented cannot be used to determine whether a regimen of hydroxychloroquine with azithromycin provides benefits in terms of disease progression or decreased infectiousness, especially for pts with more severe disease.</td>
<td></td>
<td></td>

</tbody>
</table>

**Hydroxychloroquine with azithromycin uncontrolled, observational, retrospective analysis in France (Million et al):** Data for 1061 pts with PCR-documented SARS-CoV-2 RNA who were treated with a regimen of hydroxychloroquine sulfate (200 mg 3 times daily for 10 days) and azithromycin known and potential risks associated with the use authorized by the EUA. The basis for the FDA decision to revoke the EUA for hydroxychloroquine and chloroquine is summarized below: **1)** Suggested hydroxychloroquine and chloroquine dosage regimens as detailed in the EUA fact sheets for healthcare providers are unlikely to produce an antiviral effect. **2)** Earlier observations of decreased viral shedding with hydroxychloroquine or chloroquine treatment have not been consistently replicated and recent data from a randomized controlled trial assessing probability of negative conversion showed no difference between hydroxychloroquine and standard of care alone. **3)** Current US treatment guidelines do not recommend the use of chloroquine or hydroxychloroquine in hospitalized patients with COVID-19 outside of a clinical trial and the NIH guidelines now recommend against such use outside of a clinical trial. **4)** Recent data from a large, randomized, controlled trial showed no evidence of benefit in mortality or other outcomes such as hospital length of stay or need for mechanical ventilation for hydroxychloroquine treatment in hospitalized patients with COVID-19. **Consult the FDA letter regarding the revocation of the EUA for hydroxychloroquine and chloroquine and the FDA memorandum explaining the basis for the revocation for additional information.**

<td>(500 mg on day 1, then 250 mg daily on days 2-5) were analyzed for clinical outcomes and persistence of viral shedding. Pts were included in the analysis if they received the combined regimen for at least 3 days and were clinically assessable at day 9. There were 56 asymptomatic and 1005 symptomatic pts; the majority (95%) had relatively mild disease and were considered low risk for clinical deterioration; median age was 43.6 years (range: 14-95 years) and mean time between onset of symptoms and initiation of treatment was 6.4 days. Within 10 days of treatment, good clinical outcome reported in 973 pts (91.7%) and poor clinical outcome reported in 46 pts (4.3%). Persistent nasal carriage of SARS-CoV-2 reported at completion of treatment in 47 pts (4.4%); 8 pts died.</td>

**Hydroxychloroquine (with or without azithromycin) in a retrospective analysis of patients hospitalized with COVID-19 in US Veterans Health Administration medical centers (Magagnoli et al):** Data for 368 males (median age >65 years) treated with hydroxychloroquine in addition to standard supportive management were analyzed for death rate and need for mechanical ventilation. Death rate was 27.8% (27/97) in those treated with hydroxychloroquine, 22.1% (25/113) in those treated with hydroxychloroquine and azithromycin, and 11.4% (18/158) in those not treated with hydroxychloroquine; rate of ventilation was 13.3, 6.9, and 14.1%, respectively. Use of hydroxychloroquine alone (but not use of hydroxychloroquine and azithromycin) was associated with increased overall mortality compared with no hydroxychloroquine; use of hydroxychloroquine with or without azithromycin did not reduce the risk of mechanical ventilation. Note: The pt population included only elderly males 59-75 years of age, many with significant comorbidities. This analysis did not look at efficacy measures. |         |          |

**Two different retrospective studies analyzed outcome data for hospitalized pts with confirmed COVID-19 in New York to assess the effects of treatment with hydroxychloroquine with or without** |         |          |

<td>receive hydroxychloroquine sulfate (two 800-mg doses given 6 hours apart followed by two 400-mg doses given 12 and 24 hours after the initial dose on day 1, then 400 mg every 12 hours thereafter for 9 days or until hospital discharge, whichever came first) plus standard of care and 3155 were randomized to standard of care alone. Data analyses for this intention-to-treat (ITT) population indicated that hydroxychloroquine did not reduce mortality and did not provide other benefits in pts hospitalized with COVID-19. The 28-day mortality rate was 27% in those treated with hydroxychloroquine plus standard care vs 25% in those treated with standard care alone (death rate ratio 1.09); results were consistent across all subgroups defined at the time of randomization (age, sex, race, time since illness onset, level of respiratory support, predicted 28-day risk of death). In addition, pts in the hydroxychloroquine group had a longer duration of hospitalization than those in the standard care alone group (median time to discharge 16 vs 13 days) and a lower probability of discharge alive within 28 days. Among those not receiving invasive mechanical ventilation at baseline, the number of pts who progressed to invasive mechanical ventilation or death was higher in the hydroxychloroquine group than the standard care alone group (risk ratio 1.33).&lt;sup&gt;53&lt;/sup&gt; Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. &lt;sup&gt;54&lt;/sup&gt;, &lt;sup&gt;67&lt;/sup&gt; From March 22 to June 19, 2020, 954 pts were randomized to receive hydroxychloroquine sulfate (two 800-mg doses given 6 hours apart followed by a 400-mg dose given 12 hours after the initial dose on day 1, then 400 mg twice daily for 10 days) with local standard of care and...</td>

909 pts were randomized to hydroxychloroquine control (i.e., local standard of care only). Clinical characteristics at baseline were well balanced between groups. Data analysis for the intention-to-treat (ITT) population (947 pts in hydroxychloroquine group and 906 pts in standard of care only group) indicated that hydroxychloroquine did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for hydroxychloroquine in the ITT population was 1.19; 104/947 pts treated with hydroxychloroquine (10.2%) and 84/906 pts treated with standard of care (8.9%) died. Ventilation was initiated after randomization in 75 pts receiving hydroxychloroquine and 66 pts receiving standard of care.\(^{64}\)

**Multicenter, randomized, blinded, placebo-controlled trial evaluating hydroxychloroquine in adults hospitalized with COVID-19 (Self et al):** A total of 479 adults with laboratory-confirmed SARS-CoV-2 infection were randomized 1:1 to receive hydroxychloroquine sulfate (400 mg twice daily on day 1, then 200 mg twice daily on days 2-5) or placebo. Baseline characteristics were similar between both groups; median age was 57 years and median duration of symptoms prior to randomization was 5 days. The primary outcome was clinical status at 14 days after randomization and clinical status was assessed using a 7-category ordinal scale (COVID outcomes scale); secondary outcomes included all-cause all-location mortality at 14 and 28 days after randomization, time to recovery, composite of death or need for ECMO, and support-free days through 28 days (e.g., no need for hospitalization, oxygen, intensive care, ventilator, vasopressors). At day 14, there was no difference in clinical status between the hydroxychloroquine group (242 pts) and placebo group (237 pts); median score (interquartile range) on the COVID outcomes scale was 6 (4-7) in both groups (score of 6 was defined as not hospitalized and unable to perform normal activities). There also was no difference in

\(^a\)Dosages: hydroxychloroquine sulfate (400 mg twice daily on day 1, then 200 mg twice daily on days 2-5) or placebo.
clinical status at day 14 between the hydroxychloroquine and placebo groups in any of the prespecified subgroups (e.g., based on age, sex, race/ethnicity, baseline illness severity, duration of symptoms). In addition, there were no differences in any of the secondary outcomes between the treatment groups. Data for pts with confirmed vital status at day 28 indicated that 10.4% of those in the hydroxychloroquine group and 10.6% of those in the placebo group had died.  

Retrospective, comparative cohort study evaluating clinical outcomes in hospitalized COVID-19 pts treated with hydroxychloroquine vs hydroxychloroquine with azithromycin vs azithromycin alone (Arshad et al): Data for 2541 consecutive pts with laboratory-confirmed COVID-19 who were admitted to hospitals within the Henry Ford Health System in Michigan and received hydroxychloroquine and/or azithromycin or did not receive these drugs were analyzed. Median age of patients was 64 years; the majority had BMI of 30 or greater and many had various other comorbidities; 68% received corticosteroid treatment and 4.5% received tocilizumab; mSOFA scores were not available for 25% of pts and data were not available regarding duration of symptoms prior to hospitalization; and the median length of hospitalization was 6 days. The primary end point was inpatient mortality; median follow-up was 28.5 days. Results indicated that crude mortality rates were 18.1% in the entire group, 13.5% in the hydroxychloroquine group, 20.1% in the hydroxychloroquine with azithromycin group, 22.4% in the azithromycin group, and 26.4% in those not treated with hydroxychloroquine and/or azithromycin. The primary causes of mortality were respiratory failure (88%), cardiac arrest (4%), and cardiopulmonary arrest and multi-organ failure (8%). Note: Only selected pts with minimal cardiac risk factors received hydroxychloroquine with azithromycin and all pts treated with hydroxychloroquine were monitored closely with telemetry and serial QTc evaluations.

<tr>
<td>Open-label, randomized study in hospitalized pts with mild to moderate COVID-19 (Cavalcanti et al; Brazil; NCT04322123): Adults hospitalized with COVID-19 were randomized 1:1:1 to receive standard care (control group), hydroxychloroquine (400 mg twice daily for 7 days) with standard care, or hydroxychloroquine (same dosage) plus azithromycin (500 mg once daily for 7 days) with standard care. Pts not requiring supplemental oxygen or only requiring supplemental oxygen at a rate of 4 L/min or less at baseline were enrolled; pts with a history of severe ventricular tachycardia or with QTc of 480 msec or greater at baseline were excluded. The median time from onset of symptoms to randomization was 7 days. The primary outcome was clinical status at day 15 evaluated using a 7-point ordinal scale. Data for the 504 pts in the modified intention-to-treat population with laboratory-confirmed COVID-19 (173 pts in the control group, 159 pts in the hydroxychloroquine group, 172 pts in the hydroxychloroquine and azithromycin group) indicated there was no significant difference in clinical status at day 15 in those treated with hydroxychloroquine with or without azithromycin compared with the control group. There also were no significant differences in secondary outcomes (e.g., need for mechanical ventilation, duration of hospitalization, in-hospital death) among the groups. 61</td>

Open-label, randomized study in outpatients with mild COVID-19 (Mitja et al; Spain): Total of 293 adults with laboratory-confirmed COVID-19 who did not require hospitalization and had mild symptoms (i.e., fever, acute cough, shortness of breath, sudden olfactory or gustatory loss, influenza-like illness) for less than 5 days before study enrollment were randomized 1:1 to receive hydroxychloroquine (800 mg on day 1, then 400 mg once daily for 6 days) or usual care only. The primary outcome was reduction of viral RNA load in nasopharyngeal swabs at days 3 and 7 after treatment initiation. Median age of pts was 41.6 years, 53% reported chronic health conditions, and 87% were healthcare workers. The median time from symptom onset... |
to randomization was 3 days, and the mean viral load at baseline was 7.9 log_{10} copies/mL. **Results indicated that a 7-day hydroxychloroquine regimen did not provide any clinical benefits compared with usual care alone in these outpatients with mild COVID-19.** There was no significant reduction in viral load at day 3 or 7 in those treated with hydroxychloroquine vs those treated with usual care only and there was no decrease in median time to resolution of COVID-19 symptoms (10 and 12 days, respectively) and no decrease in risk of hospitalization (7 and 6%, respectively). 59

Double-blind, randomized, placebo-controlled study in outpatients with confirmed or probable early COVID-19 (Skipper et al; US and Canada; NCT04308668): A total of 423 symptomatic adults with laboratory-confirmed COVID-19 or with symptoms compatible with COVID-19 and a high-risk exposure to a contact with laboratory-confirmed COVID-19 were randomized 1:1 to receive hydroxychloroquine (initial dose of 800 mg, 600 mg given 6-8 hours later, then 600 mg once daily for the next 4 days) or placebo. Enrolled pts had been symptomatic for no more than 4 days and did not require hospitalization at the time of enrollment. The primary efficacy end point specified in the initial study protocol was subsequently changed to overall symptom severity over 14 days; symptoms and severity were self-reported by the pts at days 3, 5, 10, and 14 using a survey with a 10-point visual analog scale. Median age of pts was 40 years, 68% reported no chronic medical conditions, 57% were healthcare workers, 25% had been exposed to COVID-19 through household contacts, and 56% of pts had enrolled within 1 day of symptom onset. **Results indicated that a 5-day hydroxychloroquine regimen did not provide any substantial improvement in symptom severity in these outpatients with confirmed or probable COVID-19.** At day 5, 54% of pts in the hydroxychloroquine group and 56% in the placebo group reported symptoms. At day 14, 24% of those treated with hydroxychloroquine had ongoing symptoms compared with 30% of those treated with placebo.
Overall, the decrease in prevalence of symptoms and the reduction in symptom severity score over 14 days were not significantly different between the two groups (symptom severity in the 10-point scale decreased 2.6 points in those treated with hydroxychloroquine and 2.3 points in those treated with placebo). In addition, there was no difference between the groups in the incidence of hospitalization or death.  

Large, multinational, retrospective study analyzed outcome data for hospitalized pts with confirmed COVID-19 to assess the effects of hydroxychloroquine or chloroquine used with or without a macrolide (Mehra et al; now retracted): Original publication included data obtained worldwide for 96,032 pts hospitalized with COVID-19 between Dec 20, 2019 and Apr 14, 2020, including 14,888 pts who received chloroquine or hydroxychloroquine with or without a macrolide (azithromycin or clarithromycin) initiated within 48 hours of diagnosis (treatment group) and 81,144 pts who did not receive these drugs (control group). Based on those data, inhospital mortality rate in the control group was 9.3% compared with 18% in those treated with hydroxychloroquine alone (n=3016), 23.8% in those treated with hydroxychloroquine and a macrolide (n=6221), 16.4% in those treated with chloroquine alone (n=1868), and 22.2% in those treated with chloroquine and a macrolide (n=3783).  

Note: This published study has now been retracted by the publisher at the request of 3 of the original authors.  

Concerns were raised with respect to the veracity of the data and analyses conducted by a global healthcare data collaborative.  

Hydroxychloroquine for postexposure prophylaxis of COVID-19 randomized, placebo-controlled trial in the US and Canada (NCT04308668): Asymptomatic adults with occupational or household exposure to an individual with COVID-19 were randomly assigned 1:1 to receive postexposure prophylaxis with a 5-day regimen of hydroxychloroquine sulfate (initial 800-mg dose followed by a 600-mg dose given 6-8
hours after first dose on day 1, then 600 mg once daily for 4 additional days) or placebo (folate tablets). A total of 821 asymptomatic adults were enrolled within 4 days after COVID-19 exposure (414 randomized to hydroxychloroquine and 407 randomized to placebo); 66% were healthcare workers. Overall, 88% of participants reported high-risk exposures (occurred at a distance of <6 feet for >10 minutes while not wearing a face mask or eye shield) and the others reported moderate-risk exposures (occurred at a distance of <6 feet for >10 minutes while wearing a face mask but no eye shield). **Note:** Participants were recruited primarily through social media outreach and traditional media platforms and were enrolled using an internet-based survey. The exposure event and subsequent onset of new symptoms and illness compatible with COVID-19 after enrollment were self-reported using email surveys on days 1, 5, 10, and 14 and at 4-6 weeks. Results of these surveys and information obtained using additional forms of follow-up indicated that confirmed or probable COVID-19 (based on self-reported symptoms or PCR testing) developed in 13% of participants overall (107/821) and did not differ significantly between those who received hydroxychloroquine prophylaxis (11.8%) and those who received placebo (14.3%). **Note:** The various limitations of the trial design should be considered when interpreting the results. Exposure to someone with confirmed COVID-19, time from the exposure event to initiation of prophylaxis, and all outcome data (including possible COVID-19 symptoms and PCR test results) were self-reported by study participants. COVID-19 was confirmed with PCR testing in only a small percentage (<3%) of participants who self-reported COVID-19 symptoms. Survey results indicated that full adherence to the 5-day prophylaxis regimen was reported by only 75% of patients randomized to hydroxychloroquine and 83% of those randomized to placebo. In addition, a total of 52 participants did not complete any surveys after study enrollment.

### Drug(s) | AHFS Class | Rationale | Trials or Clinical Experience | Dosage* | Comments
--- | --- | --- | --- | --- | ---
| Double-blind, placebo-controlled, randomized trial in the US to evaluate hydroxychloroquine for preexposure prophylaxis (PrEP) for prevention of COVID-19 (Abella et al; NCT04329923): Healthcare personnel working ≥20 hours per week in hospital-based units (nurses, physicians, certified nursing assistants, emergency technicians, respiratory therapists) who had no known history of SARS-CoV-2 infection and no symptoms suggestive of COVID-19 within 2 weeks prior to trial enrollment were randomized 1:1 to receive hydroxychloroquine (600 mg daily) or placebo for preexposure prophylaxis of COVID-19. Nasopharyngeal swab tests for SARS-CoV-2 and serologic tests for anti-nucleocapside IgG, anti-spike protein receptor-binding domain (RBD) IgM, and anti-RBD IgG were performed at the time of randomization (baseline) and at 4 and 8 weeks; participants also were surveyed weekly for adherence and adverse events. The primary outcome was rate of conversion to SARS-CoV-2-positive status based on nasopharyngeal swab testing at 8 weeks. A total of 125 participants were evaluable for the primary outcome (64 in the hydroxychloroquine arm and 61 in the placebo arm); 22 of the evaluable participants (17.6%) discontinued study treatment early. Results indicate that preexposure prophylaxis with hydroxychloroquine did not provide clinical benefits in hospital-based healthcare personnel. The rate of COVID-19 positivity was similar in the hydroxychloroquine group (6.3%) and placebo group (6.6%); cases of infection occurred throughout the 8-week study period. All 8 individuals who became infected (4 in each group) were either asymptomatic or had mild disease with full recovery; none required hospitalization. After reviewing data at the time of a second planned interim analysis, the data safety and monitoring board recommended that the trial be terminated early. Grade 3 or 4 adverse events were not reported in any participants; the incidence of adverse events was significantly higher in the hydroxychloroquine group than the placebo group (45 vs 26%). Note: Limitations of this trial include the possibility that it was insufficiently powered because of low
enrollment, data are not available to quantify the frequency of participant exposures to the virus or specific timing of such exposures, and most participants were young and healthy.  

**Efficacy of hydroxychloroquine for preexposure prophylaxis (PrEP) for prevention of COVID-19** was also evaluated in another double-blind, placebo-controlled, randomized trial in the US and Canada (Rajasingham et al; NCT04328467): This study enrolled 1483 healthcare personnel ≥18 years of age at high risk because of ongoing exposure to patients with SARS-CoV-2 (i.e., personnel working in emergency departments, intensive care units, or COVID-19 hospital wards; those performing aerosol-generating procedures; first responders) and randomized them to PrEP with hydroxychloroquine (two 400-mg doses given 6-8 hours apart, then 400 mg once or twice weekly for 12 weeks) or similar regimens of placebo (folic acid). The primary outcome was laboratory-confirmed COVID-19 or COVID-19-compatible illness. **Results indicated that a once- or twice-weekly regimen of hydroxychloroquine did not reduce laboratory-confirmed COVID-19 or COVID-19-compatible illness in healthcare personnel at high risk of infection.** Overall, COVID-19 (laboratory-confirmed or symptomatic compatible illness) occurred in 39 (7.9%) of those in the placebo group compared with 29 (5.9%) of those in the once-weekly hydroxychloroquine group and 29 (5.9%) of those in the twice-weekly hydroxychloroquine group. This corresponded to an incidence of 0.38 events/person-year with placebo compared with 0.27 events/person-year with once-weekly and 0.28 events/person-year with twice-weekly hydroxychloroquine.  

**Double-blind, placebo-controlled, randomized trial in the US to evaluate hydroxychloroquine for postexposure prophylaxis (PEP) for prevention of COVID-19 following contact with an infected individual** (Barnabas et al; NCT04328961): Trial participants were adults with known exposure to an individual with SARS-CoV-2...
infection (household or healthcare-associated exposure) within the prior 96 hours. Households were randomly assigned in a 1:1 ratio to receive PEP with hydroxychloroquine (400 mg daily for 3 days, then 200 mg daily for 11 days) or ascorbic acid as placebo equivalent (500 mg daily for 3 days, then 250 mg daily for 11 days); all eligible participants in the same household were randomly assigned to the same group to prevent unblinding between study participants. The primary end point was laboratory-confirmed SARS-CoV-2 infection through day 14. Results indicated that a 14-day hydroxychloroquine regimen was not effective for PEP in household contacts of individuals with COVID-19. A total of 689 participants were included in the modified intention-to-treat (mITT) primary analysis. A total of 98 SARS-CoV-2 infections were detected in the first 14 days of follow-up among participants who were negative at baseline. Overall, there were 53 SARS-CoV-2 acquisition events in the hydroxychloroquine group and 45 events the control group.  

Efficacy of hydroxychloroquine for postexposure prophylaxis (PEP) for prevention of COVID-19 following contact with an infected individual was also evaluated in another double-blind, placebo-controlled, randomized trial in the US and Canada (Boulware et al; NCT04308668): Trial participants were adults with household or occupational exposure to an individual with laboratory-confirmed COVID-19 at a distance of <6 feet for >10 minutes while not wearing a face mask or eye shield (high-risk exposure) or while wearing a face mask but no eye shield (moderate-risk exposure). Within 4 days of exposure, participants were randomly assigned to receive PEP with hydroxychloroquine (800-mg dose, then 600 mg 6-8 hours later, then 600 mg daily for 4 days) or placebo (folic acid). The primary outcome was laboratory-confirmed SARS-CoV-2 infection or COVID-19-related symptoms through day 14. Results indicated that hydroxychloroquine was not effective for PEP in high- or moderate-risk household or occupational contacts of an individual.

with confirmed COVID-19. A total of 821 participants (87.6% with high-risk exposures) were included in the efficacy analysis. COVID-19 (either PCR-confirmed or symptomatically compatible) developed in 107 participants (13%) during the 14 days of follow-up. The incidence of new illness compatible with COVID-19 was 11.8% in the hydroxychloroquine group and 14.3% in the placebo group. 69

**Retrospective cohort study in the US to evaluate possible SARS-CoV-2 preventive benefits of hydroxychloroquine therapy used in pts with rheumatic conditions (Gentry et al):** Possible benefit of long-term hydroxychloroquine therapy used for management of rheumatic conditions for prevention of SARS-CoV-2 infection in such pts was investigated retrospectively using data obtained from the US Veterans Affairs Medical Centers (VAMCs) database. Adults in the database with ICD-10 diagnostic code entries for rheumatoid arthritis, systemic lupus erythematosus, and associated rheumatologic conditions were identified and each such pt receiving hydroxychloroquine was matched to 2 such pts not receiving hydroxychloroquine (controls). The primary end point was the proportion of pts with PCR-confirmed SARS-CoV-2 infection between March 1 and June 30, 2020 among those receiving long-term hydroxychloroquine therapy versus the propensity-matched patients not receiving hydroxychloroquine. Data analyses indicated that long-term hydroxychloroquine therapy in patients receiving the drug for rheumatic conditions was not associated with a preventive effect against SARS-CoV-2 infection. The incidence of SARS-CoV-2 infection was similar in pts receiving hydroxychloroquine (0.3%; 31 of 10,703 pts) and those not receiving the drug (0.4%; 78 of 21,406 pts). In those who developed active SARS-CoV-2 infection, there were no significant differences in secondary outcomes between the hydroxychloroquine group and control group. 63

Various clinical trials evaluating hydroxychloroquine for treatment or prevention of COVID-19 are registered at clinicaltrials.gov. 10

<td>Neuraminidase inhibitors (e.g., oseltamivir)</td>
<td>8:18.28</td>
<td>Antivirals active against influenza viruses</td>
<td>Oseltamivir has been included as a component of various antiviral regimens used for the treatment of COVID-19.(^1), (^5), (^6), (^7) While oseltamivir is noted to have been widely used for confirmed or suspected COVID-19 cases in hospitals in China in the early stages of the pandemic, there has been no evidence that oseltamivir is effective in the treatment of COVID-19.(^2)</td>
<td>Dosage of oseltamivir in the case series of 99 COVID-19 patients was 75 mg orally every 12 hours.(^1)</td>
<td>Although oseltamivir was suggested as a potential treatment and included in various antiviral regimens used during the early stages of the COVID-19 pandemic,(^5), (^6), (^7), (^11) the drug does not appear to have in vitro activity against SARS-CoV-2 and there are no data to support the use of oseltamivir or other neuraminidase inhibitors in the treatment of COVID-19.</td>
</tr>
</tbody>
</table>

**Trials or Clinical Experience**

- **In a retrospective case series** of 99 adults with COVID-19 at a single center in Wuhan from 1/1/20 to 1/20/20, 76% of pts received antiviral treatment, including oseltamivir (75 mg orally every 12 hours). At the time of evaluation, 58% of patients remained hospitalized, 31% had been discharged, and 11% had died.\(^1\)

- **In a retrospective case series** of 79 adults with COVID-19 who were negative for influenza A and B, early use of oseltamivir had no effect on COVID-19 and did not effectively slow the progression of the disease.\(^6\)

- **In a retrospective cohort study** of 1190 adults with COVID-19 at a single center in Wuhan from 12/29/19 to 2/28/20, 61.6% of pts received antiviral therapy (e.g., oseltamivir, ganciclovir, lopinavir/ritonavir, interferon, umifenovir). A survival analysis indicated that administration of oseltamivir appeared to have reduced the risk of death in pts with severe disease and seemed to have been associated with less deterioration (i.e., progression from nonsevere to severe disease or severe disease to death).\(^7\)**

**Note:** Limitations of this study include missing laboratory data because of retrospective data extraction, lack of information on possible mixed viral infections, and inability to analyze possible reasons for mortality benefit.

- Oseltamivir may be included in some COVID-19 clinical trials registered at clinicaltrials.gov.\(^9\)

**Comments**

CDC states that, when SARS-CoV-2 and influenza are cocirculating, priority groups for influenza antiviral treatment include pts who are hospitalized with respiratory illness; outpatients with severe, complicated, or progressive respiratory illness; and outpatients at higher risk for influenza complications presenting with any symptoms of acute respiratory illness (with or without fever). CDC recommends oseltamivir for treatment of hospitalized pts with suspected or confirmed influenza and states that oseltamivir, zanamivir, or peramivir may be used for the treatment of influenza in outpatients, taking into account the severity and progression of illness and the presence of complications.\(^10\)
### Drug(s)
Remdesivir (Veklury®)

### AHFS Class
8:18.32 Antiviral

### Updated 4/30/21

### Rationale
Nucleotide analog prodrug; RNA polymerase inhibitor

Broad-spectrum antiviral with activity against various viruses, including coronaviruses

In vitro evidence of activity against SARS-CoV-2 in Vero E6 cells; 1,18 antiviral activity against SARS-CoV-2 in human airway epithelial (HAE) cells

In Rhesus macaques infected with SARS-CoV-2, treatment with a 6-day regimen of IV remdesivir initiated 12 hours after virus inoculation was associated with some benefits (lower disease severity scores, fewer pulmonary infiltrates, lower virus titers in bronchoalveolar lavage samples) compared with vehicle control; remdesivir treatment did not reduce viral loads or infectious virus titers in nose, throat, or rectal swabs compared with vehicle control

In vitro activity against SARS-CoV and MERS-CoV; active in animal models of SARS and MERS; prevented MERS in Rhesus macaques when given before infection and provided benefits when given after animal already infected

Pharmacokinetic data available from studies in healthy adults

### Trials or Clinical Experience
Randomized, double-blind, placebo-controlled trial in hospitalized adults with severe COVID-19 in China (NCT04257666; Wang et al.): Pts were randomized 2:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily on days 2-10) or placebo initiated within 12 days of symptom onset. Primary outcome was time to clinical improvement within 28 days after randomization or hospital discharge, whichever came first. ITT population included 158 pts treated with remdesivir and 78 pts treated with placebo; 32% of pts also received interferon α-2b, 28% also received LPV/RTV, and 66% also received corticosteroids during hospitalization. Median time to clinical improvement was not significantly different in remdesivir group (21 days) vs placebo group (23 days); 28-day mortality rate was similar in both groups (14% vs 13%). When remdesivir was initiated within 10 days of symptom onset, median time to clinical improvement was numerically shorter (but not statistically significant) compared with placebo group (18 vs 23 days). Duration of invasive mechanical ventilation was numerically shorter (but not statistically significant) in remdesivir group; only a small percentage of pts (0.4%) were on invasive mechanical ventilation at time of enrollment. Remdesivir did not result in significant reduction in SARS-CoV-2 viral load in nasopharyngeal, oropharyngeal, and sputum samples. Remdesivir was discontinued in 18 pts (12%) because of adverse effects. Note: Enrollment was terminated before the pre-specified number of pts was attained (lack of available pts); trial was insufficiently powered to detect assumed differences in clinical outcome.

Phase 3 randomized, open-label trial in hospitalized pts with severe COVID-19 (NCT04292899; GS-US-540-5773; SIMPLE-Severe) sponsored by the manufacturer (Gilead): Initial study protocol was designed to evaluate safety and antiviral activity of 5- and 10-day regimens of remdesivir (200 mg IV on day 1, followed by 100 mg IV once daily for total of 5 or 10 days) in conjunction with standard of care in adults with severe COVID-19 not receiving mechanical ventilation at study entry, protocol was

Remdesivir dosage for FDA-labeled indication for treatment of COVID-19 in adults and pediatric patients ≥12 years of age weighing at least 40 kg (lyophilized powder formulation or solution concentrate formulation): Loading dose of 200 mg by IV infusion on day 1, followed by maintenance doses of 100 mg by IV infusion once daily from day 2. For pts not requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days.

Emergency use authorization (EUA) remdesivir dosage for treatment of COVID-19 in pediatric patients weighing 3.5 to <40 kg (lyophilized powder formulation only): Loading dose of 5 mg/kg by IV infusion on day 1, followed by maintenance doses of 2.5 mg/kg by IV infusion once daily from day 2. For pts not requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days.

Emergency use authorization (EUA) remdesivir dosage for treatment of COVID-19 in pediatric patients <12 years of age weighing ≥40 kg (lyophilized powder formulation only): Loading dose of 200 mg by IV infusion on day 1, followed by maintenance doses of 100 mg by IV infusion once daily from day 2. For pts not requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days.

Emergency use authorization (EUA) for remdesivir: The original EUA issued by FDA on May 1, 2020 permitted use of remdesivir for treatment of COVID-19 in hospitalized adults and children with suspected or laboratory-confirmed COVID-19 and severe disease (defined as oxygen saturation [SpO2] ≤94% on room air or requiring supplemental oxygen, mechanical ventilation, or ECMO); 17 on August 28, 2020, FDA broadened the EUA to allow use of the drug in hospitalized patients irrespective of disease severity. In response

<td>The only direct-acting antiviral (DAA) currently approved by FDA for treatment of COVID-19 in certain populations. Received FDA approval on October 22, 2020 for treatment of COVID-19 in adults and pediatric patients ≥12 years of age weighing at least 40 kg who are hospitalized or in a healthcare setting capable of providing acute care comparable to inpatient hospital care. FDA states that such alternative care sites may include temporary facilities intended to provide additional hospital surge capacity/capabilities for communities overwhelmed by patients with COVID-19 and at-home care provided by hospitals that have received CMS waiver approval as part of CMS’s Acute Hospital Care at Home (AHCaH) program. The drug may be used for the FDA-labeled indication to treat patients directly to an alternative care site and, if clinically indicated, to complete the course of treatment in patients transferred to an alternative care site.</td>

<td>subsequently modified to include pts 12 years of age or older, add an extension phase, and include a cohort of pts receiving mechanical ventilation. Data for the initial 397 pts not requiring mechanical ventilation at study entry (200 received a 5-day regimen and 197 received a 10-day regimen) indicate similar clinical improvement with both treatment durations after adjusting for baseline clinical status. Pt demographics and clinical characteristics at baseline generally were similar in both groups, although the 10-day group included a higher percentage of pts in the most severe disease categories and a higher proportion of men (who are known to have worse COVID-19 outcomes than women); more pts had baseline symptoms before first dose of remdesivir was similar in both groups (8 or 9 days). At day 14, 129/200 pts (65%) in the 5-day group and 106/197 pts (54%) in the 10-day group achieved clinical improvement (defined as an improvement of at least 2 points from baseline on a 7-point ordinal scale). After adjusting for baseline imbalances in disease severity, data indicate that clinical status at day 14, time to clinical improvement, recovery, and death (from any cause) were similar in both groups. Although eligibility criteria according to the initial study protocol excluded pts receiving invasive mechanical ventilation, 4 pts in the 5-day group and 9 pts in the 10-day group were receiving invasive mechanical ventilation or ECMO (need identified after initial screening and before treatment initiation or pts were accepted as protocol deviations). There also were more pts in the 10-day group (30%) who required high-flow oxygen support at baseline compared with the 5-day group (24%). Post-hoc analysis among pts receiving mechanical ventilation or ECMO at day 5 indicate that, by day 14, 40% of such individuals who had received the 5-day regimen had died compared with 17% of those who had received the 10-day regimen. Treatment with remdesivir beyond 5 days did not appear to improve outcomes among pts who were receiving noninvasive positive-pressure ventilation or high-flow oxygen, low-flow oxygen, or breathing ambient air. Note: Results for the initial 397 study pts with severe COVID-19 not requiring mechanical ventilation and/or ECMO, recommended total treatment duration is 5 days; if pt does not demonstrate clinical improvement, treatment may be extended for up to 5 additional days (i.e., up to a total treatment duration of 10 days). For those requiring invasive mechanical ventilation and/or ECMO, recommended total treatment duration is 10 days.26 NIH COVID-19 Treatment Guidelines Panel-recommended duration of remdesivir treatment: The NIH panel recommends that hospitalized pts who require supplemental oxygen but do not require high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO, should receive remdesivir for a duration of 5 days or until hospital discharge, whichever comes first. If such pts progress to requiring high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO during such treatment, the panel recommends that the remdesivir course be completed. The panel states that there are insufficient data on the optimal duration of remdesivir treatment for pts who have not shown clinical improvement after a 5-day regimen; some experts would extend the total duration of remdesivir treatment to up to 10 days in these patients.20 to FDA approval of remdesivir for use in adults and pediatric patients ≥12 years of age weighing at least 40 kg, the EUA was reissued on October 22, 2020 to allow continued authorization of the drug (lyophilized powder formulation only) for emergency use in pediatric patients weighing 3.5 to &lt;40 kg and pediatric patients &lt;12 years of age weighing at least 3.5 kg with suspected or laboratory-confirmed COVID-19.39 The EUA for remdesivir requires that the drug be administered by a healthcare provider in an inpatient hospital setting (or alternative care site capable of providing acute care comparable to general inpatient hospital care) via IV infusion at dosages recommended in the EUA.26,39. The EUA also requires that healthcare facilities and healthcare providers administering remdesivir comply with certain mandatory record keeping and reporting requirements (including adverse event reporting to FDA MediWatch).26,39 Although distribution of remdesivir under the EUA was previously directed by the HHS Office of the Assistant Secretary for Preparedness and Response (ASPR) in collaboration with state health departments,26,38 the EUA now designates the manufacturer (Gilead) and its authorized distributor(s) as the parties responsible for distribution of the drug.39 For additional information about the remdesivir EUA, consult the EUA letter of authorization,38 EUA fact sheet for healthcare providers,38 and EUA fact sheet for parents and caregivers.37 Healthcare providers should contact Gilead’s sole US distributor (AmersiSourceBergen at 800-746-6273) to purchase remdesivir for age-appropriate use under the FDA-approved indication (lyophilized powder formulation or solution concentrate formulation) or the EUA (lyophilized powder formulation only).37 Concerns regarding variations in remdesivir packaging: The manufacturer is alerting healthcare providers that...</td>

Drug(s) | AHFS Class | Rationale | Trials or Clinical Experience | Dosage | Comments
---|---|---|---|---|---

Comparative analysis of data from phase 3 SIMPLE-Severe trial and real-world retrospective cohort of patients: The manufacturer announced results of an analysis that compared data for 312 hospitalized pts with severe COVID-19 who received remdesivir in this randomized, open-label trial with a retrospective cohort of 818 pts with similar baseline characteristics and disease severity who received standard of care treatment (without remdesivir) during the same time period. More than 90% of pts in both groups were enrolled at North American trial sites and the rest were enrolled at European or Asian trial sites. Clinical recovery (improvement in clinical status based on a 7-point ordinal scale) and mortality rate for these 2 groups were compared. By day 14, recovery was reported in 74.4% of pts treated with remdesivir and 59% of pts in the retrospective cohort treated with standard of care and the mortality rate was 7.6 and 12.5%, respectively.

Subgroup analyses of data from Phase 3 SIMPLE-Severe trial: The manufacturer announced results of subgroup analyses of 229 hospitalized pts with severe COVID-19 who received remdesivir in this randomized, open-label trial and were enrolled at US trial sites. Clinical improvement was defined as a 2-point or greater improvement on a 7-point ordinal scale. At day 14, the rate of clinical improvement was 84% in black pts (n=43), 76% in Hispanic white pts (n=17), 67% in Asian pts (n=18), 67% in non-Hispanic white pts (n=119), and 63% in pts who did not identify with any of these groups (n=32). An analysis of 397 pts who were enrolled globally indicated that black race, age less than 65 years, treatment outside of Italy, and requirement of only low-flow oxygen support or room air at baseline were factors significantly associated with clinical improvement of at least 2 points on day 14. Another subgroup analysis was performed to evaluate outcomes in pts who received concomitant therapy with mechanical ventilation at study entry cannot be extrapolated to critically ill pts receiving mechanical ventilation.

The NIH COVID-19 Treatment Guidelines Panel issued the following recommendations for use of remdesivir (with or without dexamethasone) for the management of COVID-19 based on disease severity:

1) Hospitalized with moderate COVID-19 not requiring supplemental oxygen: The panel states that data are insufficient to recommend either for or against routine use of remdesivir. For pts at high risk of disease progression, use of remdesivir may be appropriate.

2) Hospitalized requiring supplemental oxygen but not requiring high-flow oxygen, noninvasive ventilation, invasive mechanical ventilation, or ECMO: The panel recommends remdesivir (e.g., for pts requiring minimal supplemental oxygen) or remdesivir plus dexamethasone (e.g., for pts requiring increasing amounts of supplemental oxygen) or dexamethasone alone (e.g., when combination therapy with remdesivir is unavailable or cannot be used). In rare circumstances when corticosteroids cannot be used, the panel states that remdesivir plus baricitinib can be used instead of remdesivir plus dexamethasone (see Baricitinib in this Evidence Table). The panel recommends against use of remdesivir plus dexamethasone plus baricitinib, except in a clinical trial.

There are variations in remdesivir packaging and labeling (e.g., use of the tradename Veklury®, expiration dates) depending on whether the drug was originally manufactured for use under the EUA or for commercial use. FDA states that, if patient safety can be assured, they do not intend to object to remdesivir supplies that have labels specifying “for use under Emergency Use Authorization” being distributed for appropriate use under the FDA-labeled indication during the first six months after the drug received this approval. Questions related to carton or vial labeling or expiration dates should be directed to Gilead at 866-633-4474 or www.askgileadmedical.com.

The work of the ASHP COVID-19 Treatment Guidelines Panel is intended to be current as of the date of issuance and is subject to change as new data and information become available. The panel states that it is not the intention of this treatment guide to include all possible conditions, diseases, or circumstances when corticosteroids cannot be used, the panel states that remdesivir plus baricitinib can be used instead of remdesivir plus dexamethasone (see Baricitinib in this Evidence Table). The panel recommends against use of remdesivir plus dexamethasone plus baricitinib, except in a clinical trial.

| remdesivir and hydroxychloroquine vs those who received only remdesivir. At a median follow-up of 14 days, the rates and likelihood of recovery were lower in those treated with both drugs (57%) compared with those treated with remdesivir alone (69%). Although concomitant hydroxychloroquine was not associated with increased mortality at 14 days, the overall rate of adverse effects was higher and, after adjusting for baseline variables, the incidence of grade 3-4 adverse events was significantly higher in those treated with both drugs.  

**Phase 3 randomized, open-label trial in hospitalized pts with moderate COVID-19** (NCT04292730; GS-US-540-5774; SIMPLE-Moderate) sponsored by the manufacturer (Gilead): Initial study protocol was designed to evaluate safety and antiviral activity of 5- and 10-day regimens of remdesivir (200 mg IV on day 1, followed by 100 mg IV once daily for total of 5 or 10 days) in conjunction with standard of care compared with standard care alone in adults with moderate COVID-19 (i.e., hospitalized with evidence of pulmonary infiltrates and SpO₂ > 94% on room air); protocol was subsequently modified to change the primary end point to clinical status on day 11 based on a 7-point ordinal scale, include pts 12 years of age or older, and add an extension phase to include additional pts.  

Data for the initial group of adults who received a 5-day regimen of remdesivir with standard care (n=191), 10-day regimen of the drug with standard care (n=193), or standard care alone (n=200) have been published. At day 11, 70, 65, or 61% of pts in the 5-day, 10-day, or standard care alone group, respectively, had clinical improvement based on at least a 2-point improvement from baseline on a 7-point ordinal scale.Pts in the 5-day remdesivir group had statistically significant higher odds of a better clinical status distribution on the 7-point scale on day 11 than those receiving standard care (odds ratio: 1.65) but the difference was of uncertain clinical importance; the difference in clinical status distribution between pts in the 10-day remdesivir group and the standard care group was not statistically significant. At day 11, 4 deaths were reported in

3) **Hospitalized requiring high-flow oxygen or noninvasive ventilation:** The panel recommends dexamethasone or dexamethasone plus remdesivir. The panel **recommends against** use of remdesivir alone. In rare circumstances when corticosteroids cannot be used, the panel states that baricitinib plus remdesivir can be used (see Baricitinib in this Evidence Table). The panel **recommends against** use of remdesivir plus dexamethasone plus baricitinib, except in a clinical trial.  

4) **Hospitalized requiring invasive mechanical ventilation or ECMO:** The panel recommends dexamethasone. Dexamethasone plus remdesivir may be considered for pts who were recently intubated. The panel **recommends against** use of remdesivir alone.  

5) **Not hospitalized, mild to moderate disease:** The panel states that data are insufficient to recommend either for or against any specific antiviral or antibody therapy. The panel states that dexamethasone should **not** be used. (See Corticosteroids [Systemic] in this Evidence Table.)  

Although safety and efficacy of combined use of remdesivir with dexamethasone or other corticosteroids have not been specifically studied in clinical trials to date, the NIH panel states that there are theoretical reasons that such combined therapy may be beneficial in some pts with severe COVID-19. Concomitant use of remdesivir with dexamethasone is expected to result in minimal or no reduction in remdesivir exposure.  

**IDSA issued the following recommendations for use of remdesivir in hospitalized pts:**  

**1) Hospitalized with SpO₂ > 94% on room air without need for supplemental oxygen:** IDSA suggests against routine use of remdesivir. Additional study needed to assess benefits and harms of remdesivir in pts with moderate COVID-19.  

---

| Remdesivir | 30 | **2) Hospitalized with severe COVID-19 (i.e., SpO₂ ≤94% on room air and requiring supplemental oxygen, mechanical ventilation, or ECMO):** IDSA suggests use of remdesivir over no anti-viral treatment. Based on available data, these experts recommend remdesivir be prioritized for those with severe, but not critical, COVID-19. IDSA also suggests use of dexamethasone in pts with severe, but noncritical, COVID-19 and recommends use of dexamethasone in critically ill pts (see Corticosteroids [Systemic] in this Evidence Table). If corticosteroids cannot be used with remdesivir, these experts suggest use of baricitinib with remdesivir rather than remdesivir alone (see Baricitinib in this Evidence Table). IDSA states that a 10-day remdesivir regimen may be desirable in those on mechanical ventilation, but a 5-day regimen is suggested in those on supplemental oxygen but not on mechanical ventilation. 25
| Pregnant women: The NIH panel states that remdesivir should not be withheld from pregnant women if it is otherwise indicated. 20 The manufacturer states that available data from published case reports and compassionate use of remdesivir are insufficient to evaluate for a drug-associated risk of major birth defects, miscarriage, or adverse maternal or fetal outcomes. 46
| Concomitant use of remdesivir and chloroquine or hydroxychloroquine is not recommended; 20, 26, 33, 46 FDA warns that there is in vitro evidence that chloroquine antagonizes intracellular metabolic activation and antiviral activity of remdesivir. 26
<p>| Remdesivir clinical drug interaction studies have not been performed to date. In vitro studies indicate remdesivir is a substrate for cytochrome P-450 (CYP) isoenzyme 3A4, organic anion transporting polypeptide (OATP) 1B1, and P-glycoprotein (P-gp), and is an inhibitor of CYP3A4, OATP1B1, OATP1B3, and multidrug and toxin extrusion transporter (MATE) 1. | <strong>30</strong> Phase 3 adaptive, randomized, double-blind, placebo-controlled trial [NCT04280705; NIAID Adaptive COVID-19 Treatment Trial 1 (ACTT-1)] in hospitalized adults with COVID-19: Pts were randomized 1:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily on days 2-10 or until hospital discharge or death) or placebo. All pts received supportive care according to the standard of care for the trial site hospital. The primary outcome was time to recovery, defined as the first day within 28 days after enrollment when clinical status met criteria for category 1, 2, or 3 on an 8-category ordinal scale (i.e., discharged from hospital with or without limitations on activities or requirement for home oxygen, or hospitalized but not requiring supplemental oxygen and no longer requiring ongoing medical care). A total of 1062 pts were randomized with 541 assigned to remdesivir and 521 assigned to placebo (intention-to-treat population). Baseline demographics and clinical characteristics (e.g., age, disease severity, comorbidities at study enrollment, time to initiation of treatment after symptom onset) were similar in both groups. A total of 957 pts (90.1%) had severe disease (i.e., required mechanical ventilation, required supplemental oxygen, had SpO₂ ≤94% on day 1, then 100 mg IV once daily on days 2-10 or until hospital discharge or death) or placebo. All pts received supportive care according to the standard of care for the trial site hospital. The primary outcome was time to recovery, defined as the first day within 28 days after enrollment when clinical status met criteria for category 1, 2, or 3 on an 8-category ordinal scale (i.e., discharged from hospital with or without limitations on activities or requirement for home oxygen, or hospitalized but not requiring supplemental oxygen and no longer requiring ongoing medical care). A total of 1062 pts were randomized with 541 assigned to remdesivir and 521 assigned to placebo (intention-to-treat population). Baseline demographics and clinical characteristics (e.g., age, disease severity, comorbidities at study enrollment, time to initiation of treatment after symptom onset) were similar in both groups. A total of 957 pts (90.1%) had severe disease (i.e., <strong>Note:</strong> Effect of remdesivir on SARS-CoV-2 viral load was not assessed. Limitations of this study include the open-label design and use of an ordinal scale to evaluate outcomes that was not ideal for detecting differences in pts with moderate COVID-19. 30 |</p>

<td>room air, or had tachypnea with respiratory rate ≥24 breaths/minute at study enrollment, and the median time from symptom onset to randomization was 9 days (range: 6-12 days). Final trial data indicated shorter median time to recovery in the remdesivir group (10 days) vs the placebo group (15 days); recovery rate ratio 1.29. Those who received remdesivir were more likely to have clinical improvement at day 15 than those who received placebo (odds ratio 1.5). Kaplan-Meier estimates of mortality by day 15 were 6.7% in the remdesivir group vs 11.9% in the placebo group (hazard ratio 0.55); by day 29, mortality was 11.4 and 15.2%, respectively (hazard ratio 0.73). Posthoc analysis of efficacy based on disease severity at enrollment suggested that benefits of remdesivir were most apparent in hospitalized pts receiving low-flow oxygen (recovery rate ratio 1.45); the recovery rate ratio in the subgroup of pts on mechanical ventilation or ECMO at enrollment was 0.98. 42 There was no observed benefit of remdesivir compared with placebo in the subgroup with mild to moderate disease (defined as SpO₂ &gt;94% on room air or a respiratory rate &lt;24 beats/minute without supplemental oxygen) at enrollment; however, the number of pts in this subgroup was relatively small. Although there was no observed difference in time to recovery in subgroups requiring high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO at enrollment, the trial was not powered to detect differences in outcomes within subgroups and there is uncertainty about the effects of remdesivir on the course of COVID-19 in patients who are mechanically ventilated or on ECMO. 20 Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (NCT04315948; SOLIDARITY): The protocol-specified primary outcome was in-hospital mortality; protocol-specified secondary outcomes were initiation of ventilation and...</td>

<td>duration of hospitalization. 44, 53 From March 22 to October 4, 2020, 2750 pts were randomized to receive remdesivir (200 mg on day 1, then 100 mg on days 2-10) with local standard of care and 2725 pts were randomized to remdesivir control (i.e., local standard of care only). Clinical characteristics at baseline were well balanced between groups. Data analysis for the intention-to-treat (ITT) population (2743 pts in remdesivir group and 2708 pts in standard of care group) indicated that remdesivir did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for remdesivir in the ITT population was 0.95; 301/2743 pts treated with remdesivir (12.5%) and 303/2708 pts treated with standard of care (12.7%) died. Ventilation was initiated after randomization in 295 pts in the remdesivir group and 284 pts in the standard of care group. 44 Data from the manufacturer’s compassionate use program (adults): Preliminary data are available for a cohort of 53 adults from multiple sites in the US, Italy, Japan, and other countries who were hospitalized with severe COVID-19 and received treatment with remdesivir; 40 pts received the full 10-day regimen (200 mg IV on day 1, then 100 mg IV on days 2-10), 10 pts received 5-9 days and 3 pts received less than 5 days of treatment with the drug. At baseline, 30 pts (57%) were receiving mechanical ventilation and 4 (18%) were receiving extracorporeal membrane oxygenation (ECMO). Over a median follow-up of 18 days after first dose, 36 pts (68%) showed clinical improvement based on oxygen-support status and 8 pts (15%) worsened. There were 7 deaths (13%), including 6 pts receiving invasive ventilation. Adverse effects (e.g., increased hepatic enzymes, diarrhea, rash, renal impairment, hypotension) were reported in 32 pts (60%); 12 pts (23%) had serious adverse effects (e.g., multiple organ dysfunction syndrome, septic shock, acute kidney injury, hypotension); 4 pts (8%) discontinued the drug.</td>

| the most common adverse events were due to underlying disease and most laboratory abnormalities were grades 1–2.  
  Phase 2/3 single-arm, open-label trial in pediatric patients (NCT04431453; CARA-VAN): The manufacturer (Gilead) initiated a trial to evaluate safety, tolerability, pharmacokinetics, and efficacy of remdesivir in pediatric pts (birth to <18 years of age) with laboratory-confirmed COVID-19.  
  Phase 3 adaptive, randomized, double-blind trial compared a regimen of remdesivir alone vs a regimen of remdesivir with baricitinib in hospitalized adults (NCT04401579; ACTT-2): Pts were randomized 1:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily for a total treatment duration of 10 days or until hospital discharge) with either baricitinib (4 mg once daily orally or through a nasogastric tube for 14 days or until hospital discharge) or 14-day regimen of oral placebo. The primary end point was time to recovery through day 29 (defined as discharged without limitations on activities, discharged with limitations on activities and/or requiring home oxygen, or still hospitalized but not requiring supplemental oxygen and no longer requiring ongoing medical care). Data for the 1033 pts in the intention-to-treat (ITT) population (515 in the remdesivir and baricitinib group and 518 in the remdesivir alone group) indicate that those who received the combined regimen were more likely to have better clinical outcomes than those who received remdesivir alone. Based on results of this trial and other data, FDA issued an emergency use authorization (EUA) for baricitinib to permit use of the drug in combination with remdesivir for treatment of suspected or laboratory-confirmed COVID-19 in hospitalized adults and pediatric pts ≥2 years of age. (See Baricitinib in this Evidence Table.) |
| Phase 3 adaptive, randomized, double-blind trial to compare a regimen of remdesivir alone vs a regimen of remdesivir with interferon beta-1a |

<td>(NCT04492475; ACTT-3): This iteration of NIAID’s Adaptive COVID-19 Treatment Trial (ACTT) is evaluating possible benefits of using interferon beta-1a in conjunction with remdesivir in hospitalized adults with laboratory-confirmed SARS-CoV-2 infection. Inclusion criteria include evidence of lung involvement (radiographic infiltrates, SpO(_2) of 94% or lower on room air, or requiring supplemental oxygen or mechanical ventilation); exclusion criteria include need for ECMO, prior treatment with ≥3 doses of remdesivir, treatment with any interferon preparation within the previous 2 weeks, prior treatment with convalescent plasma or IGIV or various other drugs used for management of COVID-19. Pts will be randomized 1:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily for the duration of hospitalization up to 10 days total) with either sub-Q interferon beta-1a (44 mcg once daily on days 1, 3, 5, and 7 during hospitalization for a total of 4 doses) or placebo. Randomized, double-blind trial to compare a regimen of remdesivir alone vs a regimen of remdesivir with tocilizumab (NCT04409262; REMDACTA): This trial is evaluating possible benefits of using tocilizumab (an interleukin-6 [IL-6] inhibitor) in conjunction with remdesivir in hospitalized patients 12 years of age or older with severe COVID-19 pneumonia. Pts will be randomized to receive remdesivir (IV loading dose on day 1, then once-daily IV maintenance doses on days 2-10) with either tocilizumab (single IV infusion on day 1) or placebo. Phase 3 randomized, double-blind, placebo-controlled, adaptive trial sponsored by NIAID to evaluate safety, tolerability, and efficacy of a regimen of remdesivir vs a regimen of remdesivir with investigational SARS-CoV-2 immune globulin (anti-SARS-CoV-2 hyperimmune globulin intravenous [hIGIV]) in hospitalized adults (NCT04546581; ITAC): Pts with documented COVID-19 and duration of symptoms ≤12 days will be randomized to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily for 9 days) with either hIGIV (2000 mg IV on day 1, then 1000 mg IV on days 2-11) or placebo.</td>

</table>
| SARS-CoV-2-Specific Monoclonal Antibodies | 8:18.24 Monoclonal Antibodies | Monoclonal antibodies (mAbs) used in the treatment or prevention of infectious diseases are engineered versions of antibodies naturally produced by the immune system in response to invading viruses or other pathogens.  
  mAbs that are specific for certain infectious agents or their toxins (e.g., respiratory syncytial virus, *Bacillus anthracis*, *Clostridiodes difficile*) have been used for the treatment or prevention of infections caused by these agents.  
  Animal studies evaluating neutralizing mAbs specific for other coronaviruses (SARS-CoV-1, MERS-CoV) have demonstrated benefits in such models.  
  SARS-CoV-2-specific mAbs are designed to directly target the virus and may act as neutralizing antibodies (nAbs). Most SARS-CoV-2-specific mAbs being investigated target epitopes on the spike protein (S protein) of the virus | Clinical trials have been initiated to evaluate several different SARS-CoV-2-specific mAbs, including the following:  
  Casirivimab and Imdevimab (REGN10933 and REGN10987; REGN-COV2):  
  Randomized, placebo-controlled, phase 1/phase 2/phase 3 trial sponsored by the manufacturer (Regeneron) to evaluate safety, tolerability, and efficacy of a single IV dose of casirivimab and imdevimab for treatment of COVID-19 in hospitalized adults (NCT04426695).  
  Randomized, placebo-controlled, phase 2/phase 3 trial sponsored by the manufacturer (Regeneron) to evaluate safety, tolerability, and efficacy of a single IV dose of casirivimab and imdevimab for treatment of COVID-19 in hospitalized adults (NCT04426695).  
  Initial study protocol included 4 different cohorts of pts (i.e., on low-flow oxygen, not requiring oxygen, on high-flow oxygen without mechanical ventilation, on mechanical ventilation) to be randomized to receive casirivimab and imdevimab (administered together) or placebo.  
  The manufacturer announced that further enrollment of hospitalized pts requiring high-flow oxygen or mechanical ventilation was terminated following a recommendation from the independent data monitoring committee (IDMC) based on a potential safety signal and unfavorable risk/benefit profile in such pts. Enrollment of hospitalized pts not requiring oxygen or on low-flow oxygen is continuing as recommended by the IDMC.  
  Because mAbs generally have long half-lives, it is likely that only a single dose of the SARS-CoV-2-specific mAbs may be required.  
  Bamlanivimab (LY-CoV555) and Etesevimab (LY-CoV016):  
  Emergency use authorization (EUA) dosage and administration of bamlanivimab and etesevimab for treatment of mild to moderate COVID-19 in adults and pediatric pts ≤12 years of age weighing ≤40 kg with positive results of direct SARS-CoV-2 viral testing who are outpatients and are at high risk for progressing to severe COVID-19 and/or hospitalization:  
  Single dose of 700 mg of bamlanivimab and 1.4 g of etesevimab administered together after dilution as a single IV infusion; administer in an outpatient setting as soon as possible after positive viral test for SARS-CoV-2 and within 10 days of symptom onset.  
  Casirivimab and Imdevimab (REGN10933 and REGN10987):  
  Emergency use authorization (EUA) dosage and administration of casirivimab and imdevimab for treatment of mild to moderate COVID-19 in adults and pediatric pts ≤12 years of age weighing ≤40 kg with positive results of direct | mg IV once daily during hospitalization for up to 10 days total) with either placebo or investigational anti-SARS-CoV-2 hIGIV (single IV dose of 400 mg/kg).  
  (See Immune Globulin in this Evidence Table.)  
  Phase 3 randomized, double-blind, placebo-controlled trial to evaluate efficacy and safety of remdesivir for treatment of COVID-19 in outpatients (NCT 04501952): Manufacturer (Gilead) initiated a study to evaluate a 3-day regimen of IV remdesivir in adults and pediatric pts ≥12 years of age with early-stage COVID-19 to determine efficacy in an outpatient setting for reducing the rate of hospitalization or death. | SARS-CoV-2-specific mAbs are not commercially available.  
  Safety and efficacy of investigational SARS-CoV-2-specific mAbs for the treatment or prevention of COVID-19 have not been established.  
  Although results of controlled clinical trials are needed to provide additional information on safety and efficacy of mAbs that specifically target SARS-CoV-2, preliminary data suggest that outpatients may benefit from receiving a SARS-CoV-2-specific mAb early in the course of the infection and it has been suggested that such mAbs may offer some advantages over other immunotherapies used for the treatment of COVID-19 (e.g., COVID-19 convalescent plasma, IGIV) in terms of specificity and safety.  
  Bamlanivimab (LY-CoV555):  
  Effective April 16, 2021, FDA revoked the EUA for use of bamlanivimab alone (monotherapy) for the treatment of mild to moderate COVID-19.  
  Because a sustained increase in SARS-CoV-2 viral variants in the US that are resistant to bamlanivimab alone and because testing technologies are not available to enable healthcare providers to test individual COVID-19 patients for SARS-CoV-2 viral variants prior to initiation of mAB treatment, there is an increased... |
and block the receptor-binding domain (RBD) of the S protein from interacting with human angiotensin-converting enzyme 2 (ACE2), thereby preventing the virus from entering cells and inhibiting viral replication. 1, 16, 25, 27, 28

SARS-CoV-2-specific mAbs potentially could limit or modify SARS-CoV-2 infection and may be effective for both treatment and prevention since such mAbs could provide immediate and longer-term (weeks or months) protection against the virus. 1, 3, 30

Various mAbs specific for SARS-CoV-2 are being investigated for the treatment and prevention of COVID-19, including the following:

**Casirivimab and Imdevimab (REGN10933 and REGN10987; REGN-COV2):** Combination of two different recombinant neutralizing IgG1 mAbs (casirivimab and imdevimab) that bind to non-overlapping epitopes on the S protein RBD of SARS-CoV-2 and block the virus from binding to the human ACE2 receptor. 21, 25, 27, 29, 40 Preclinical studies demonstrated neutralizing activity in vitro and SARS-CoV-2 effects against SARS-CoV-2 infection and viral replication in animal models. 21, 27, 28

**Bamlanivimab (LY-CoV555; LY3819253):** Recombinant neutralizing IgG1 mAb that specifically binds to an epitope on the S protein of SARS-CoV-2 or similar device) and were randomized to receive 2.4 g of casirivimab and imdevimab (1.2 g of each mAb; low dose), 8 g of casirivimab and imdevimab (4 g of each mAb; high dose), or placebo in addition to standard of care (67% received remdesivir and 74% received systemic corticosteroids). Results of the preliminary analysis (i.e., futility analysis) indicated that the mAb regimen had sufficient efficacy to warrant continuing the trial. Data for the 217 pts seronegative for endogenous antibodies against SARS-CoV-2 at baseline indicated that casirivimab and imdevimab treatment reduced the time-weighted average daily viral load through day 7 by -0.54 log_{10} copies/mL and through day 11 by -0.63 log_{10} copies/mL (nominal p = 0.002 for combined doses). Data for the 270 pts seropositive at baseline indicated that clinical and virologic benefit of the mAb treatment was limited in these pts (time-weighted average viral load through day 7 reduced by -0.20 log_{10} copies/mL for combined doses). Efficacy of the low- and high-dose regimens of casirivimab and imdevimab was similar. 60

Randomized, placebo-controlled, phase 1/phase 2/phase 3 trial sponsored by the manufacturer (Regeneron) to evaluate safety, tolerability, and efficacy of a single IV dose of casirivimab and imdevimab (administered together) for treatment of COVID-19 in outpatients (NCT04425629). 73 Results of a preplanned interim analysis that included the first 275 outpatients enrolled in the phase 1/phase 2 portion of this trial have been published. Enrolled pts were randomized 1:1:1 to receive a single IV infusion of 2.4 g of casirivimab and imdevimab (1.2 g of each mAb; low dose) or 8 g of casirivimab and imdevimab (4 g of each mAb; high dose), or placebo in addition to standard of care. All pts had COVID-19 infection confirmed by testing ≤72 hour prior to randomization and had symptom onset ≤7 days prior to randomization. Results of this interim analysis indicated that casirivimab and imdevimab reduced viral load and there was a positive trend in reduction of medical visits; benefits were greatest in those who had not mounted their own effective immune response. 58

SARS-CoV-2 viral testing who are outpatients and are at high risk for progressing to severe COVID-19 and/or hospitalization: Single dose of 1.2 g of casirivimab and 1.2 g of imdevimab administered together after dilution as a single IV infusion; administer in an outpatient setting as soon as possible after positive viral test for SARS-CoV-2 and within 10 days of symptom onset. 65

Concerns about medication errors and variations in packaging: The manufacturer is alerting healthcare providers that casirivimab and imdevimab are packaged individually in separate cartons and vials, but must be combined and administered together after dilution as a single IV infusion only. Beginning in February 2021, casirivimab and imdevimab are being shipped in “dose packs” with the tradename REGENCOV®; although there are 4 different dose pack presentations, each contains a sufficient number of cartons and vials of the drugs to prepare a single treatment dose. Although some cartons and vials of the drugs may be labeled “for intravenous infusion or subcutaneous injection”, 52 the drugs must be administered together by IV infusion only as specified in the EUA. 49, 52 Casirivimab and imdevimab may each be supplied as two different vial sizes (1332 mg/11.1 mL or 300 mg/2.5 mL). 49, 52 Instructions for preparing the casirivimab and imdevimab solution for IV infusion (e.g., number of vials) specified in the EUA fact sheet for healthcare providers must be followed to ensure the correct dose. 49 Some cartons and vials of casirivimab and imdevimab may be labeled REGN10933 and REGN10987, respectively. 49, 52

Risk of treatment failure if bamlanivimab is administered alone. Therefore, based on the totality of scientific evidence available, FDA concluded that the known and potential benefits of bamlanivimab alone no longer outweigh the known and potential risks of monotherapy with the drug. Note: The EUA for bamlanivimab in a combined regimen with etesevimab remains unchanged. Healthcare facilities that have existing supplies of bamlanivimab alone, distributed prior to revocation of the EUA for use of the drug as monotherapy, should contact the authorized US distributor (AmerisourceBergen) to obtain etesevimab to pair with their existing supplies of bamlanivimab to enable use under the EUA for bamlanivimab and etesevimab. 51, 82

Bamlanivimab (LY-CoV555) and Etesevimab (LY-CoV016): FDA issued an Emergency Use Authorization (EUA) for bamlanivimab and etesevimab on February 9, 2021 that permits combined use of the drugs for the treatment of mild to moderate COVID-19 in adults and pediatric pts ≥12 years of age weighing ≥40 kg with positive results of direct SARS-CoV-2 viral testing who are outpatients and are at high risk for progressing to severe COVID-19 and/or hospitalization. FDA states that, based on a review of data from an ongoing randomized, double-blind, placebo-controlled phase 2/3 trial in outpatients with mild to moderate COVID-19 (BLAZE-1; NCT04427501), it is reasonable to believe that bamlanivimab and etesevimab administered together may be effective for the treatment of mild to moderate COVID-19 in adults and pediatric patients ≥12 years of age weighing ≥40 kg with positive results of direct SARS-CoV-2 viral testing who are at high risk for progressing to severe COVID-19 and/or hospitalization and, when used under the conditions of the EUA, the known and potential benefits of bamlanivimab and etesevimab administered together for treatment...

**Trials or Clinical Experience**

**Dosage**

**Comments**

Casirivimab and Imdevimab (REGN10933 and REGN10987):

FDA issued an Emergency Use Authorization (EUA) for casirivimab and imdevimab on November 23, 2020 that permits combined use of these drugs for the treatment of mild to moderate COVID-19 in adults and pediatric pts ≥12 years of age weighing ≥40 kg with positive results of direct SARS-CoV-2 viral testing who are outpatients and are at high risk for progressing to severe COVID-19 and/or hospitalization. FDA states that, based on a review of phase 1/2 data from an ongoing randomized, double-blind, placebo-controlled, phase 1/2/3 trial of casirivimab and imdevimab in outpatients with mild to moderate COVID-19 (NCT04425629), it is reasonable to believe that casirivimab and imdevimab administered together may be effective for the treatment of mild to moderate COVID-19 in adults and pediatric patients ≥12 years of age weighing ≥40 kg with positive results of direct SARS-CoV-2 viral testing who are at high risk for progressing to severe COVID-19 and/or hospitalization and, when used under the conditions of the EUA, the known and potential benefits of casirivimab and imdevimab for treatment of COVID-19 in such pts outweigh the known and potential risks. 48, 49

The EUAs for currently available SARS-CoV-2-specific mAbs define pts at high risk for progressing to severe COVID-19 and/or hospitalization as those who meet at least one of the following criteria: BMI ≥35, chronic kidney disease, diabetes, immunosuppressive disease, immunosuppressive treatment; ≥65 years of age; ≥55 years of age with cardiovascular disease or hypertension or COPD or other chronic respiratory disease; 12-17 years of age with BMI ≥85th percentile for their age and gender based on CDC growth charts, sickle cell

### Drug(s) | AHFS Class | Rationale | Trials or Clinical Experience | Dosage | Comments
--- | --- | --- | --- | --- | ---
Bamlanivimab and Etesevimab | | | portion of this ongoing study have been published. At the time of the interim analysis, data were available for 452 outpatients ≥18 years of age with mild or moderate COVID-19 (309 pts randomized to bamlanivimab and 143 randomized to placebo). Based on the primary outcome (change in SARS-CoV-2 viral load from baseline to day 11 assessed by RT-PCR of nasopharyngeal swabs), only the 2.8-g dose group had lower viral load than the placebo group; decreased viral load at day 11 did not appear to be a clinically meaningful end point since viral load was substantially reduced from baseline for the majority of pts, including those in the placebo group. A final analysis of data for 309 adults randomized to the 3 bamlanivimab monotherapy arms, 112 adults randomized to the bamlanivimab and etesevimab combination arm (single IV infusion containing 2.8 g of each mAb), and 156 adults randomized to placebo have now been published. There was a statistically significant difference in change in SARS-CoV-2 viral load from baseline to day 11 in the bamlanivimab and etesevimab group compared with placebo; however, the change in viral load in each of the 3 bamlanivimab monotherapy dosage groups was not significantly different compared with placebo. At day 29, the proportion of pts with hospitalizations or emergency department visits related to COVID-19 was 1-2% in the bamlanivimab monotherapy groups, 0.9% in the bamlanivimab and etesevimab group, and 5.8% in the placebo group. Randomized, double-blind, placebo-controlled phase 2 study evaluating various mAb regimens for treatment of mild to moderate COVID-19 in outpatients (NCT04634409; BLAZE-4): Certain treatment arms evaluated bamlanivimab with etesevimab. Pts were randomized to receive a single IV infusion of bamlanivimab 700 mg and etesevimab 1.4 g (158 patients), bamlanivimab 2.8 g and etesevimab 2.8 g (101 patients), bamlanivimab 700 mg alone (103 patients), or placebo (153 patients). The primary end point was the proportion of pts with SARS-CoV-2 viral load by cycle threshold (CT) greater than 5.27 on bamlanivimab and etesevimab, or casirivimab and imdevimab comply with certain mandatory record keeping and reporting requirements (including adverse event reporting to FDA MedWatch). The EUAs for the SARS-CoV-2-specific mAbs were each reissued to require that manufacturers establish a process for monitoring genomic databases for emergence of global viral variants of SARS-CoV-2 and, if requested by FDA, assess activity of the drugs against any global SARS-CoV-2 variants of interest. The EUA fact sheets for healthcare providers for each currently available mAb includes information on specific variants and resistance. Information on SARS-CoV-2 viral variants circulating in the US collected through CDC’s national genomic surveillance program is available at https://www.cdc.gov/coronavirus/2019-ncov/cases-updates/variant-proportions.html and may help guide treatment decisions. Allocation of currently available SARS-CoV-2-specific mAbs for use under their respective EUAs is being directed by the HHS Office of the Assistant Secretary for Preparedness and Response (ASPR) in collaboration with state and territorial health departments and the manufacturers. Healthcare providers should contact the authorized US distributor (AmerisourceBergen) to obtain these mAbs. Information on specific locations in the US administering the drugs may be available at the HHS protect public data hub (https://protect-public.hhs.gov/pages/therapeutics-distribution) or National Infusion Center Association (NICA) website (https://covid.infusioncenter.org) or National Infusion Center Association (NICA) website (https://covid.infusioncenter.org). Bamlanivimab and Etesevimab: For additional information about the EUA, consult the bamlanivimab and etesevimab EUA letter of authorization, EUA fact sheet for healthcare providers, and EUA fact sheet for patients, parents and caregivers.
day 7. Initial results indicate the two different dosage regimens of bamlanivimab and etesevimab result in similar virologic outcomes. Day 7 data (range 7–9 days) indicate that 31% of the placebo group still had viral load by CT greater than 5.27 compared with 14% of the group treated with bamlanivimab 700 mg and etesevimab 1.4 g and 10% of the group treated with bamlanivimab 2.8 g and etesevimab 2.8 g. 63

Randomized, double-blind, placebo-controlled phase 3 trial initiated by the manufacturer (Eli Lilly) in collaboration with NIAID is evaluating efficacy and safety of bamlanivimab used alone or with etesevimab for prevention of SARS-CoV-2 infection in adult residents and staff of skilled nursing or assisted living facilities (NCT04497987; BLAZE-2). 11 The manufacturer (Eli Lilly) announced results of data analyses for 965 study participants who tested negative for SARS-CoV-2 at baseline (299 residents and 666 staff) and were randomized to receive prophylaxis with bamlanivimab (4.2 g as a single dose) or placebo. At 8 weeks of follow-up, there was a significantly lower frequency of symptomatic COVID-19 (the primary end point) overall in the bamlanivimab group vs the placebo group (odds ratio 0.43). Subgroup analyses for the 299 residents also indicated a significantly lower frequency of symptomatic COVID-19 in the bamlanivimab group vs the placebo group (odds ratio 0.20); there were 4 deaths attributed to COVID-19 in the residents and all occurred in the placebo group. 62

Multicenter, adaptive, randomized, placebo-controlled, phase 3 trial evaluating safety and efficacy of various therapeutics for hospitalized pts with COVID-19 sponsored by NIAID (NCT04501978; TICO; ACTIV-3): Trial included a treatment arm to evaluate bamlanivimab with standard of care vs placebo with standard of care in hospitalized adults. 46, 41 NIAID announced that the bamlanivimab treatment arm was terminated following a recommendation from the independent data and safety monitoring board (DSMB) based on low likelihood of clinical benefit in hospitalized pts. 41 Data for the 314 enrolled pts is calculated from the day 7 data. Initial results indicate the two different dosage regimens of bamlanivimab and etesevimab result in similar virologic outcomes. Day 7 data (range 7–9 days) indicate that 31% of the placebo group still had viral load by CT greater than 5.27 compared with 14% of the group treated with bamlanivimab 700 mg and etesevimab 1.4 g and 10% of the group treated with bamlanivimab 2.8 g and etesevimab 2.8 g. 63

Randomized, double-blind, placebo-controlled phase 3 trial initiated by the manufacturer (Eli Lilly) in collaboration with NIAID is evaluating efficacy and safety of bamlanivimab used alone or with etesevimab for prevention of SARS-CoV-2 infection in adult residents and staff of skilled nursing or assisted living facilities (NCT04497987; BLAZE-2). 11 The manufacturer (Eli Lilly) announced results of data analyses for 965 study participants who tested negative for SARS-CoV-2 at baseline (299 residents and 666 staff) and were randomized to receive prophylaxis with bamlanivimab (4.2 g as a single dose) or placebo. At 8 weeks of follow-up, there was a significantly lower frequency of symptomatic COVID-19 (the primary end point) overall in the bamlanivimab group vs the placebo group (odds ratio 0.43). Subgroup analyses for the 299 residents also indicated a significantly lower frequency of symptomatic COVID-19 in the bamlanivimab group vs the placebo group (odds ratio 0.20); there were 4 deaths attributed to COVID-19 in the residents and all occurred in the placebo group. 62

** NIH COVID-19 Treatment Guidelines Panel states that, based on data available to date, use of bamlanivimab and etesevimab or casirivimab and imdevimab is recommended for treatment of outpatients with mild to moderate COVID-19 who are at high risk of clinical progression as defined by the EUA criteria. These experts state that SARS-CoV-2-specific mAb treatment should be given as soon as possible after COVID-19 diagnosis is confirmed by positive SARS-CoV-2 antigen or nucleic acid amplification test (NAAT) and within 10 days after symptom onset. The panel recommends against use of SARS-CoV-2-specific mAbs in pts hospitalized because of COVID-19, except in a clinical trial; however, such treatment should be considered in those with mild to moderate COVID-19 who are hospitalized for reasons other than COVID-19 but who otherwise meet the EUA criteria. Although data are not available regarding the comparative efficacy and safety of bamlanivimab and etesevimab vs casirivimab and imdevimab and it is not known whether in vitro susceptibility data correlate with clinical outcomes, some panel members would preferentially use casirivimab and imdevimab in regions where SARS-CoV-2 variants with reduced in vitro susceptibility to bamlanivimab and etesevimab are common. 57

** IDSA suggests use of bamlanivimab and etesevimab or casirivimab and imdevimab rather than no SARS-CoV-2-specific mAb treatment in outpatients with mild to moderate COVID-19 at high risk for progression to severe disease since expected benefits likely outweigh any potential harms. These experts state that susceptibility of local

<td>bamlanivimab</td>
<td></td>
<td></td>
<td>included in the prespecified interim futility assessment have been published. Enrolled pts were hospitalized with documented SARS-CoV-2 infection (duration of symptoms ≤12 days, no end-organ failure at baseline) and randomized 1:1 to receive bamlanivimab (163 pts) or placebo (151 pts). Pts also received remdesivir (95% of pts), corticosteroids (49% of pts), and supplemental oxygen when indicated. The futility assessment evaluated pulmonary function on day 5 based on a 7-category ordinal scale and indicated that a single IV infusion of bamlanivimab did not result in better clinical outcomes at day 5 compared with placebo. The odds ratio of being in a more favorable category in the bamlanivimab group compared with the placebo group was 0.85 (95% CI, 0.56 to 1.29; P = 0.45). Among 167 pts who were followed for at least 28 days or died within 28 days, 82 or 79% in the bamlanivimab or placebo group, respectively, had sustained recovery (rate ratio 1.06). The percentage of patients with the primary safety outcome (a composite of death, serious adverse events, or clinical grade 3 or 4 adverse events through day 5) was similar in the bamlanivimab and placebo group (19% and 14%, respectively). 59</td>
<td>VIR-7831 (GSK4182136): Manufacturer (Vir Biotechnology) in collaboration with GlaxoSmithKline initiated a randomized, double-blind, placebo-controlled, phase 2/phase 3 trial to assess safety, tolerability, efficacy, and pharmacokinetics of a single IV dose of VIR-7831 for treatment of mild or moderate COVID-19 in outpatients at high risk of disease progression (NCT04545060; COMET-ICE). 14, 15 The manufacturers announced that interim results of the ongoing phase 3 portion of this study (not peer reviewed) indicate that a single IV dose of VIR-7831 (500 mg) reduced the risk of hospitalization or death by 85% compared with placebo. 78 Randomized, double-blind, placebo-controlled phase 2 study evaluating various mAb regimens for treatment in adult outpatients with mild to moderate COVID-19</td>
<td>SARS-CoV-2 variants may be considered when choosing the most appropriate SARS-CoV-2-specific mAb treatment. 58 Pregnant women: NIH panel states that currently available SARS-CoV-2-specific mAbs should not be withheld from a pregnant woman who has a condition that poses a high risk of progression to severe COVID-19 if the clinician thinks that the potential benefits outweigh potential risks. 57</td>

<td>(NCT04634409; BLAZE-4):</td>
<td></td>
<td></td>
<td>One treatment arm is evaluating a regimen of bamlanivimab with VIR-7831 (SARS-CoV-2-specific mAbs that bind to different regions of the S protein of SARS-CoV-2). The primary outcome measure is the percentage of pts with SARS-CoV-2 viral load &gt;5.27 on day 7. The manufacturers (Lilly, VIR Biotechnology, and GlaxoSmithKline) announced that preliminary data (not peer reviewed) indicate that a single-dose regimen of IV bamlanivimab (700 mg) and VIR-7831 (500 mg) met the primary end point. The combined regimen resulted in a 70% relative reduction in persistently high viral load (&gt;5.27; CT &lt;27.5) at day 7 compared with placebo. In addition, the combined regimen resulted in a statistically significant reduction in the key virologic secondary end point (i.e., mean change in viral load from baseline to days 3, 5, and 7) compared with placebo. By day 29, there were no COVID-19-related hospitalizations or fatalities in either the bamlanivimab and VIR-7831 group or the placebo group.</td>

</table>
| **Retrospective cohort study** in 33 adults with COVID-19 in China suggests more favorable outcome with LPV/RTV plus umifenovir vs LPV/RTV alone: Primary end point was negative conversion in nasopharyngeal samples and progression or improvement of pneumonia. At 7 days, SARS-CoV-2 undetectable in nasopharyngeal specimens in 12/16 pts (75%) treated with LPV/RTV plus umifenovir vs 6/17 pts (35%) treated with LPV/RTV alone; at 14 days, undetectable in 15/16 pts (94%) treated with both drugs vs 9/17 pts (53%) treated with LPV/RTV alone. At 7 days, chest CT scans were improving in 11/16 pts (69%) treated with both drugs vs 5/17 pts (29%) treated with LPV/RTV alone. 5  

**Retrospective cohort study** in 81 hospitalized, non-ICU adults with COVID-19 in China found no difference in clearance of SARS-CoV-2 virus between pts receiving umifenovir vs those who did not. At 7 days, SARS-CoV-2 undetectable in pharyngeal specimens in 33/45 pts (73.3%) treated with umifenovir vs 28/36 pts (77.8%) who did not receive umifenovir. No difference in median time from onset of symptoms to negative SARS-CoV-2 test (18 vs 16 days). 9  

**Open-label, prospective, randomized, multicenter study** in 236 adults with COVID-19 in China (ChiCTR200030254): When favipiravir was compared with umifenovir, clinical recovery rate was greater in those treated with favipiravir than in those treated with umifenovir. 6 (See Favipiravir in this Evidence Table.)  

**Randomized, single-center, partially blinded trial in China** (NCT0425885) evaluated efficacy of umifenovir in conjunction with standard care vs LPV/RTV in conjunction with standard care vs standard care without an antiviral in hospitalized adults with mild/moderate COVID-19. 2, 10 Data for the 86 enrolled pts suggest no difference in mean time for positive-to-negative conversion of SARS-CoV-2 nucleic acid in respiratory specimens and no difference in clinical outcomes between pts treated with umifenovir or LPV/RTV compared with no antiviral therapy. 10 |

| Anakinra (Kineret®) Updated 4/15/21 | 92:36 Disease-modifying Anti-rheumatic Drug | Recombinant human interleukin-1 (IL-1) receptor antagonist<sup>1</sup> | There are case study data but no known published prospective clinical trial evidence supporting efficacy or safety of anakinra for treatment of COVID-19<sup>7</sup> | Various dosage regimens are being studied<sup>1,8</sup> | Some studies under way in Europe are evaluating 100 mg given subcutaneously once to 4 times daily for 7 to 28 days or until hospital discharge<sup>3</sup>  
A retrospective cohort study in Italy compared high-dose anakinra by IV infusion (5 mg/kg twice daily) and low-dose anakinra (100 mg twice daily) given subcutaneously<sup>9</sup>  
(Note: Anakinra is approved only for subcutaneous administration in the U.S.)<sup>1,7</sup>  
NIH COVID-19 Treatment Guidelines Panel states that there are insufficient clinical data to recommend either for or against use of anakinra in the treatment of COVID-19<sup>7</sup>  
Safety profile: Well established in adults with sepsis and has been studied extensively in severely ill pediatric patients with complications of rheumatologic conditions; pediatric data on use in acute respiratory distress syndrome/sepsis are limited<sup>7</sup>  
Pregnancy: Limited evidence to date: unintentional first trimester exposure considered unlikely to be harmful<sup>7</sup> |

IL-1 levels are elevated in patients with COVID-19; anakinra may potentially combat cytokine release syndrome (CRS) symptoms in severely ill COVID-19 patients<sup>2,3,4,7</sup>  
Anakinra has been used off-label for severe chimeric antigen receptor T cell (CAR T-cell)-mediated cytokine release syndrome (CRS) and macrophage activation syndrome (MAS)/secondary hemophagocytic lymphohistiocytosis. IL-1 levels are elevated in patients with these conditions. Case reports and series describe a favorable response to anakinra in these syndromes, including survival benefit in sepsis and reversing cytokine storm in adults with MAS after tocilizumab failure.<sup>7</sup>  
France: A cohort study (Ana-COVID) included a prospective cohort of 52 adults with severe COVID-19 treated with anakinra plus standard of care and a historical comparison group of 44 patients who received standard and supportive care at Groupe Hospitalier Paris Saint-Joseph. Inclusion criteria included severe COVID-19-associated bilateral pneumonia on chest x-ray or lung CT scan, laboratory-confirmed SARS-CoV-2 or typical lung infiltrates on a lung CT scan, and an oxygen saturation of ≤93% under oxygen ≥6 L/min or deterioration (saturation ≤93% under oxygen 3 L/min with loss of 3% oxygen saturation in ambient air over previous 24 hours). Anakinra was given subcutaneously in a dosage of 100 mg twice daily on days 1–3, then 100 mg once daily from day 4–10<sup>3,8,9</sup>  
A retrospective cohort study in Italy compared high-dose anakinra by IV infusion (5 mg/kg twice daily) and low-dose anakinra (100 mg twice daily) given subcutaneously<sup>9</sup>  
Italy: Retrospective cohort study (part of NCT04318366) with high- or low-dose anakinra in adults with COVID-19, moderate to severe acute respiratory distress syndrome (ARDS), and hyperinflammation (defined as elevated serum C-reactive protein [CRP] and/or ferritin levels) managed with non-invasive ventilation outside of the ICU at a Milan hospital. Patients received standard therapy (hydroxychloroquine and lopinavir/ritonavir) and either high-dose anakinra (5 mg/kg twice daily by IV infusion for a
median of 9 days followed by daily low-dose subcutaneous administration [100 mg twice daily] for 3 additional days to prevent relapse) or low-dose anakinra (100 mg twice daily subcutaneously) and were compared with a historical cohort of patients who did not receive anakinra. At 21 days, high-dose anakinra was associated with reduced CRP levels and progressive improvement in respiratory function in 21 of 29 (72%) of patients; 5 patients (17%) were placed on mechanical ventilation and 3 patients (10%) died. High-dose IV anakinra appeared to be relatively well tolerated. Anakinra was discontinued in the low-dose subcutaneous anakinra group after 7 days because of a lack of improvement in CRP levels and clinical status. In the standard treatment alone group (retrospective cohort), 8 out of 16 patients (50%) showed respiratory improvement at 21 days; 1 patient (6%) was placed on mechanical ventilation and 7 patients (44%) died. 10

Various clinical trials evaluating anakinra alone or in conjunction with other drugs for treatment of COVID-19 are registered at clinicaltrials.gov. 3

<td>Azithromycin</td>
<td>8:12.12</td>
<td>Antibacterial with some in vitro activity against some viruses (e.g., influenza A H1N1, Zika)</td>
<td>Some evidence of in vitro activity against SARS-CoV-2 in infected Vero E6 and Caco-2 cells; clinical importance unclear</td>
<td>Adjunctive therapy in certain respiratory viral infections: Although contradictory results reported, some evidence of beneficial immunomodulatory or anti-inflammatory effects when used in pts with some viral infections (e.g., influenza). However, in a retrospective cohort study in critically ill pts with laboratory-confirmed MERS, there was no statistically significant difference in 90-day mortality rates or clearance of MERS-CoV RNA between those who received macrolide therapy and those who did not. Adjunctive therapy in certain respiratory conditions: Some evidence of beneficial immunomodulatory or anti-inflammatory effects when used in pts with certain respiratory conditions (e.g., ARDS). In a retrospective cohort study in pts with moderate or severe ARDS, a statistically significant improvement in 90-day survival was reported in those who received adjunctive azithromycin.</td>
<td>Adjunctive treatment in certain viral infections: 500 mg once daily has been used. COVID-19: 500 mg on day 1, then 250 mg once daily on days 2-5 or 500 mg once daily for 7 days has been used in conjunction with a 5-, 7-, or 10-day regimen of hydroxychloroquine. Only limited information available regarding the frequency and microbiology of bacterial pulmonary coinfections or superinfections in pts with COVID-19. Empiric coverage for bacterial pathogens has been used, but is not required in all pts with confirmed COVID-19-related pneumonia. If bacterial pneumonia or sepsis is strongly suspected or confirmed, empiric antibacterial treatment should be administered. Although data are limited, bacterial pathogens in COVID-19 pts with community-acquired pneumonia (CAP) are likely the same as those seen in other pts with CAP. Therefore, if antibacterial coverage for CAP is indicated in COVID-19 pts, the usually recommended regimens for empiric treatment of CAP should be used.</td>

<td>Azithromycin</td>
<td>30</td>
<td>For the treatment of COVID-19</td>
<td>Clinical experience in pts with COVID-19: Has been used for antibacterial coverage in hospitalized pts with COVID-19</td>
<td></td>
<td>Data from various randomized, controlled clinical trials and retrospective studies have not shown evidence of clinical benefit when azithromycin was used alone or in conjunction with hydroxychloroquine for the treatment of COVID-19 in hospitalized pts.</td>
</tr>
</tbody>
</table>
was clinical status at day 15 based on a 6-level ordinal scale that ranged from not hospitalized (1) to death (6); the key secondary outcome was mortality at day 29. Results for the modified intention-to-treat (mITT) population (i.e., those with confirmed COVID-19) indicated that addition of azithromycin to standard of care was not superior to standard of care alone. At day 15, there was no difference in the proportional odds of being in higher categories on the 6-point ordinal scale between the azithromycin group and control group. At day 29, 42% of pts in the azithromycin group and 40% of those in the control group had died. There also was no difference between the groups in the proportion of pts with QTc interval prolongation (20% in azithromycin group and 21% in control group). 34

Azithromycin in randomized, controlled, open-label, adaptive, platform trial (NCT04381936; RECOVERY): This study is enrolling pts with suspected or confirmed COVID-19 from 176 hospitals in the UK. In the azithromycin arm (now terminated), 2582 pts were randomized to receive azithromycin (500 mg by mouth, NG tube, or IV once daily for 10 days or until discharge, whichever came first) plus standard of care and 5181 pts were randomized to standard of care alone. The primary outcome was all-cause mortality at day 28. Results of this study indicated that azithromycin is not an effective treatment for pts hospitalized with COVID-19. There was no difference in the 28-day mortality rate between the azithromycin plus standard of care group and the standard of care alone group (22% in both groups). In addition, the time to hospital discharge was similar (median 10 days in the azithromycin group and 11 days in the standard of care alone group) and, in those not requiring mechanical ventilation at baseline, azithromycin did not decrease the risk of progression to mechanical ventilation or death (25% in azithromycin group vs 26% in standard of care alone group). Results were consistent across all prespecified pt subgroups (age; sex; ethnicity; and symptom duration, level of respiratory support, and drugs are used sequentially. The panel states that use of doxycycline (instead of azithromycin) should be considered for empiric therapy of atypical pneumonia in COVID-19 pts receiving hydroxychloroquine (or chloroquine). 21

The benefits and risks of a combined regimen of azithromycin and hydroxychloroquine (or chloroquine) should be carefully assessed; if the regimen is used, diagnostic testing and monitoring are recommended to minimize risk of adverse effects, including drug-induced cardiac effects. 20-21, 25-28, 33 (See Hydroxychloroquine in this Evidence Table.)
Azithromycin in randomized, controlled, open-label, adaptive, platform trial in the UK (PRINCIPLE): Adult outpatients with PCR-confirmed or suspected COVID-19 and ongoing symptoms for ≤14 days who were considered at increased risk of adverse outcomes (i.e., ≥55 years of age or ≥50 years of age with at least one comorbidity) were randomly assigned to various interventions with usual care or usual care alone. Patients randomized to the azithromycin intervention arm received oral azithromycin (500 mg once daily for 3 days) with usual care, and results were compared with those for pts randomized to usual care alone. The two coprimary end points were time to first self-reported recovery and COVID-19-related hospital admission or death (both end points measured within 28 days after randomization). **Results of this study indicated that use of azithromycin in symptomatic outpatients with known or suspected COVID-19 did not provide benefits in terms of reducing time to recovery or risk of hospitalization.** A Bayesian primary analysis for 500 pts treated with azithromycin and usual care and 823 pts treated with usual care alone indicated that 80% of those who received azithromycin and 77% of those who received usual care alone reported feeling recovered within 28 days (median time to first reported recovery was 7 and 8 days, respectively); 3% of pts in each group were hospitalized within 28 days; there were no deaths in either group. **Enrollment in the azithromycin arm of the study was terminated when analyses indicated the prespecified criterion for futility was met.**

Various clinical trials evaluating azithromycin alone or in conjunction with other drugs for treatment of COVID-19 are registered at clinicaltrials.gov.
### Baricitinib (Olumiant®)

**Drug(s)**: Baricitinib

**AHFS Class**: 92:36 Disease-modifying Anti-rheumatic Drug

**Rationale**: Janus kinase (JAK) 1 and 2 inhibitor; disrupts regulators of endocytosis (AP2-associated protein kinase 1 [AAK1] and cyclin G-associated kinase [GAK]), which may help reduce viral entry and inflammation; also may interfere with intracellular virus particle assembly.

Inhibits JAK1 and JAK2-mediated cytokine release; may combat cytokine release syndrome (CRS) in severely ill patients.

Ability to inhibit a variety of proinflammatory cytokines, including interferon, has been raised as a possible concern with the use of JAK inhibitors in the management of hyperinflammation resulting from viral infections such as COVID-19.

<tr>
<td>Therapeutic dosages of baricitinib (2 or 4 mg orally once daily) are sufficient to inhibit AAK1.</td>
<td>Emergency use authorization (EUA) for baricitinib in combination with remdesivir: FDA issued an EUA on November 19, 2020 that permits use of baricitinib in combination with remdesivir for treatment of suspected or laboratory-confirmed COVID-19 in hospitalized adults and pediatric patients ≥2 years of age requiring supplemental oxygen, invasive mechanical ventilation, or extracorporeal membrane oxygenation (ECMO). FDA states that data are insufficient to recommend either for or against the use of baricitinib in combination with remdesivir in hospitalized patients when corticosteroids can be used. In rare circumstances when corticosteroids cannot be used, the panel recommends use of baricitinib in combination with remdesivir for the treatment of COVID-19 in hospitalized nonintubated patients who require oxygen supplementation. (See Remdesivir in this Evidence Table.)</td>
</tr>
</tbody>
</table>

**Dosage**: Baricitinib data that were reviewed included laboratory-confirmed SARS-CoV-2 infection with at least one of the following: radiographic infiltrates by imaging, SpO2 ≤94% on room air, or requiring supplemental oxygen, mechanical ventilation, or ECMO. Patients were randomized 1:1 to receive remdesivir (200 mg IV on day 1, then 100 mg IV once daily for a total treatment duration of 10 days or until hospital discharge) with either baricitinib (4 mg orally once daily for 14 days or until hospital discharge) with either baricitinib (4 mg orally or through a nasogastric tube once daily for 14 days or until hospital discharge) or placebo. The primary end point was time to recovery through day 29 (defined as discharged without limitations on activities, discharged with limitations on activities and/or requiring home oxygen, or still hospitalized but not requiring supplemental oxygen and no longer requiring ongoing medical care). Data for 1033 patients in the intent-to-treat population (515 in the remdesivir and baricitinib group and 518 in the remdesivir alone group) indicate that those who received the combined regimen were more likely to have better clinical outcomes than those who received remdesivir alone. Use of the combined regimen of remdesivir and baricitinib met the primary end point of reduced time to recovery. Baricitinib was well tolerated with no serious adverse events reported. At week 1 and week 2, patients who received baricitinib had significant improvement in respiratory function parameters and none of the patients required ICU support.

**Phase 3 adaptive, randomized, double-blind trial compared a regimen of remdesivir alone vs a regimen of remdesivir with baricitinib in hospitalized adults (NCT04401579; ACTT-2): Inclusion criteria included laboratory-confirmed COVID-19 in hospitalized adults (NCT04401579; ACTT-2): **

- Inclusion criteria included laboratory-confirmed SARS-CoV-2 infection with at least one of the following: radiographic infiltrates by imaging, SpO2 ≤94% on room air, or requiring supplemental oxygen, mechanical ventilation, or ECMO. **Emergency use authorization (EUA) for baricitinib in combination with remdesivir: FDA issued an EUA on November 19, 2020 that permits use of baricitinib in combination with remdesivir for treatment of suspected or laboratory-confirmed COVID-19 in hospitalized adults and pediatric patients ≥2 years of age requiring supplemental oxygen, invasive mechanical ventilation, or ECMO. FDA states that data are insufficient to recommend either for or against the use of baricitinib in combination with remdesivir for the treatment of suspected or laboratory-confirmed COVID-19 in hospitalized adults and pediatric patients ≥2 years of age requiring supplemental oxygen, invasive mechanical ventilation, or ECMO. FDA states that data are insufficient to recommend either for or against the use of baricitinib in combination with remdesivir for the treatment of COVID-19 in hospitalized nonintubated patients who require oxygen supplementation. (See Remdesivir in this Evidence Table.)

**NIH COVID-19 Treatment Guidelines Panel states that data are insufficient to recommend either for or against the use of baricitinib in combination with remdesivir for the treatment of COVID-19 in hospitalized patients when corticosteroids can be used. In rare circumstances when corticosteroids cannot be used, the panel recommends use of baricitinib in combination with remdesivir for the treatment of COVID-19 in hospitalized nonintubated patients who require oxygen supplementation. (See Remdesivir in this Evidence Table.)**
recovery compared with use of remdesivir alone (median time to recovery was 7 days in those receiving the combined regimen vs 8 days in those receiving remdesivir). Patients treated with combined remdesivir and baricitinib were also more likely to have a better clinical status at day 15 compared with those receiving remdesivir alone. The proportion of patients who progressed to ventilation (noninvasive or invasive) by day 29 was lower in patients receiving combined remdesivir and baricitinib. In addition, the mortality rate at day 29 was 4.7% in those treated with the combined regimen and 7.1% in those treated with remdesivir alone. Based on results of this trial and other data, FDA issued an emergency use authorization (EUA) for baricitinib that permits use of the drug in combination with remdesivir.

Adaptive phase 2/3 clinical trial: Open-label study planned to evaluate safety and efficacy of baricitinib in hospitalized patients with COVID-19 (NCT04340232)

A randomized, double-blind, placebo-controlled, phase 3 trial (COV-BARRIER; NCT04421027) sponsored by the manufacturer (Lilly) is currently under way to evaluate the efficacy and safety of baricitinib in hospitalized adults with COVID-19 who have at least one elevated marker of inflammation but do not require mechanical ventilation upon study entry. Targeted enrollment is 400 patients; study will be conducted in the U.S., Europe, and Latin America. Patients in the baricitinib treatment arm will receive an oral dosage of 4 mg daily for up to 14 days or until hospital discharge in addition to their background therapy.

Various clinical trials evaluating baricitinib alone or in conjunction with other drugs for treatment of COVID-19 are registered at clinicaltrials.gov.

The panel recommends against the use of baricitinib without remdesivir, except in a clinical trial. The panel states that there are insufficient data to recommend either for or against use of baricitinib in combination with corticosteroids for the treatment of COVID-19. Because both baricitinib and corticosteroids are potent immunosuppressants, there is potentially an additive risk of infection.

NIH COVID-19 Treatment Guidelines Panel states that use of baricitinib is not recommended in patients with hepatic or renal impairment (GFR <60 mL/min/1.73 m²) (see Dosage).

Minimal interaction with CYP enzymes and drug transporters and low protein binding of baricitinib allow for combined use with antiviral agents and many other drugs; however, dosage adjustment recommended when used with strong OAT3 inhibitors.
### Drug(s) | AHFS Class | Rationale | Trials or Clinical Experience | Dosage | Comments
--- | --- | --- | --- | --- | ---
Colchicine | 92:16 Antigout Agents | Exerts broad anti-inflammatory and immunomodulatory effects through multiple mechanisms, including inhibition of NOD-like receptor protein 3 (NLRP3) inflammasome assembly and disruption of cytoskeletal functions through inhibition of microtubule polymerization. | Limited anecdotal experience and clinical trial data reported to date in COVID-19; results pending from multiple clinical trials. On March 5, 2021, researchers announced that enrollment into the colchicine arm of the RECOVERY trial had been halted on the advice of the data monitoring committee (DMC) when a preliminary analysis revealed no difference in mortality between hospitalized patients receiving colchicine for treatment of COVID-19 and those receiving usual care alone; full data are not available yet, but the researchers stated that the DMC found no convincing evidence that further recruitment would provide conclusive proof of worthwhile mortality benefit overall or in any prespecified subgroup. | Dosage in NCT04326790 (GRECCO-19): Colchicine loading dosage: 1.5 mg followed in 1 hour by 0.5 mg (reduced to a single 1-mg dose in those receiving azithromycin); maintenance dosage: 0.5 mg twice daily (reduced to 0.5 mg once daily in those weighing <60 kg) until hospital discharge or maximum of 21 days. | Safety and efficacy for treatment of COVID-19 not established. The potential for toxic doses of colchicine to affect alveolar type II pneumocytes (which may inhibit surfactant release and contribute to ARDS) and increase the risk of multiple-organ failure and disseminated intravascular coagulation (DIC) has been raised as a possible concern with the use of colchicine in COVID-19 patients. **

** NIH COVID-19 Treatment Guidelines Panel** states that there are insufficient data to recommend either for or against use of colchicine for the treatment of nonhospitalized patients with COVID-19. The COLCORONA trial did not reach its primary efficacy end point of reducing hospitalizations and death, although a slight reduction in hospitalizations was observed in the subset of patients with CRP-confirmed disease. **

** NIH COVID-19 Treatment Guidelines Panel** recommends against use of colchicine in hospitalized patients for the treatment of COVID-19, except in a clinical trial. **

** Pregnancy:** Limited data are available on use of colchicine during pregnancy; data are lacking on use in pregnant women with acute COVID-19. Fetal risk cannot be ruled out. **

** Pediatric use:** Colchicine use in children is limited mainly to treatment of familial Mediterranean fever; data are lacking on use for treatment of acute COVID-19 or multisystem inflammatory syndrome in children (MIS-C). **

---

Potential to limit COVID-19-related myocardial damage also has been hypothesized based on the drug’s mechanisms of action and promising results of ongoing research on colchicine in various cardiac conditions. Several single-center, proof-of-concept or small comparative cohort studies conducted in hospitalized patients with COVID-19 suggest beneficial effects of colchicine on mortality and other clinical outcomes; in one observational study (not peer reviewed), mortality rate in patients with COVID-19 pneumonia was numerically lower in those receiving colchicine compared with those not receiving the drug, but the effect of the drug was not statistically significant; 80% of patients in the study received corticosteroids. The studies had substantial limitations, and larger well-designed studies are needed to further evaluate efficacy. Open-label, randomized, 16-hospital clinical trial (NCT04326790, GRECCO-19) in hospitalized adults with RT-PCR-confirmed SARS-CoV-2 infection; indication for and duration of colchicine use were unknown. Retrospective review of computerized healthcare database found no difference in baseline use of colchicine (0.53 vs 0.48%) between patients with a positive RT-PCR result for SARS-Cov-2 (n = 1317) and those with a negative result (n = 13,203), suggesting a lack of protective effect for colchicine against SARS-Cov-2 infection; indication for and duration of colchicine use were unknown. In experimental models of acute respiratory distress syndrome/acute lung injury (ARDS/ALI), the NLRP3 inflammasome had a major role in the development of lung injury.

NLRP3 inflammasome activation results in release of interleukins, including IL-1β, IL-6, IL-18, and chemokines. May combat the hyper-inflammatory state of COVID-19 (e.g., cytokine storm) by suppressing proinflammatory cytokines and chemokines.

SARS-CoV-1 envelope (E) protein, a viroporin involved in replication and virulence, activates the NLRP3 inflammasome in vitro in Vero E6 cells by forming calcium-permeable ion channels, leading to increased IL-1β production.
COVID-19: 55 patients received colchicine plus standard treatment and 50 received standard treatment alone; colchicine was administered orally as a loading dose of 1.5 mg followed in 1 hour by 0.5 mg (reduced to a single 1-mg dose in those receiving azithromycin) followed by a maintenance dosage of 0.5 mg twice daily (reduced to 0.5 mg once daily in those weighing <60 kg) until hospital discharge or for a maximum of 21 days. Most patients also received chloroquine or hydroxychloroquine (98%) and azithromycin (92%). **Clinical deterioration (2-grade increase on a 7-grade ordinal scale)** was observed in a greater proportion of control patients than colchicine-treated patients (7 patients [14%] vs 1 patient [1.8%]); cumulative 10-day event-free survival was higher with colchicine than with control (97 vs 83%). Baseline score on the 7-grade scale was 3 or 4 in 97% of study patients. No difference observed between the groups in baseline or peak high-sensitivity cardiac troponin or peak C-reactive protein concentration. Small number of clinical events limited the statistical robustness of the results.  

**Interim analysis (not peer reviewed) of a single-center, randomized, double-blind, placebo-controlled trial in hospitalized adults with moderate to severe, RT-PCR-confirmed COVID-19 with pneumonia (not requiring ICU admission):** Analysis of first 38 patients randomized 1:1 to colchicine or placebo indicated **shorter duration of oxygen supplementation (3 vs 7 days) and shorter hospital stay (6 vs 8.5 days)** in colchicine group vs placebo group. One patient in each group required ICU admission. Median duration of symptoms prior to treatment was 9 days (colchicine group) or 7 days (placebo group). Colchicine dosage was 0.5 mg 3 times daily for 5 days, then 0.5 mg twice daily for 5 days (initial dose was 1 mg if body weight ≥80 kg); dosage was reduced for renal impairment. Standard concomitant treatment included 7-day azithromycin regimen, up to 10-day hydroxychloroquine regimen, and heparin with or without methylprednisolone (depending on oxygenation status).

#### Nonhospitalized Patients:

**Uncontrolled case series:** 9 patients in community setting with COVID-19 received colchicine (1 mg orally every 12 hours on day 1, then 1 mg daily until third day of temperature <37.5°C); colchicine was initiated at a median of 8 days (range: 6-13 days) after symptom onset and after 3-5 days of spiking fever despite acetaminophen or antibiotic treatment. Defervescence occurred within 72 hours in all patients. One patient was hospitalized because of persistent dyspnea and discharged after 4 days of oxygen therapy. Basis for diagnosis of COVID-19 not stated. 16

**Phase 3, randomized, double-blind, placebo-controlled study (NCT04322682; COL-CORONA) [not peer reviewed]:** A total of 4488 adult outpatients (including 4159 patients with PCR-confirmed COVID-19) with at least 1 high-risk criterion were randomized within 24 hours of COVID-19 diagnosis to receive colchicine (0.5 mg twice daily for 3 days, then 0.5 mg once daily for 27 days) or placebo. The mean time from symptom onset to enrollment was 5.3 days. The primary end point was the composite of death or hospitalization due to COVID-19 within 30 days after randomization. Investigators (not the data safety monitoring board) decided to halt enrollment for logistical reasons prior to reaching the target of 6000 patients. In the intention-to-treat population, colchicine did not result in a statistically significant reduction in the composite end point of death or hospitalization due to COVID-19 compared with placebo (4.7 vs 5.8%, respectively) or in the individual end points of death, hospitalization due to COVID-19, or need for mechanical ventilation. In those with PCR-confirmed COVID-19, a statistically significant difference was observed between the colchicine and placebo groups in the composite end point of death or hospitalization (4.6 vs 6%, respectively) and in the rate of hospitalization, but not in the individual end points of death or need for mechanical ventilation. Pulmonary embolism occurred in 11 patients receiving colchicine compared with 2 placebo recipients. 24, 25

<tr>
<td>Corticosteroids</td>
<td>68:04 Adrenals</td>
<td>Potent anti-inflammatory and antifibrotic properties; use of corticosteroids may prevent an extended cytokine response and may accelerate resolution of pulmonary and systemic inflammation in pneumonia. Evidence suggests that cytokine storm, a hyperinflammatory state resembling secondary hemophagocytic lymphohistiocytosis (HLH), is a contributing factor in COVID-19-associated mortality. Immunosuppression from corticosteroids has been proposed as a treatment option for such hyperinflammation. May improve dysregulated immune response caused by sepsis (possible complication of infection with COVID-19), and increase BP when low.</td>
<td>Other registered randomized, parallel-group studies are evaluating the effects of colchicine on various outcome measures (e.g., mortality, markers of myocardial damage, clinical status, need for mechanical ventilation, duration of hospitalization) in patients with COVID-19.</td>
<td>The NIH COVID-19 Treatment Guidelines recommend an IV or oral Dexamethasone dosage of 6 mg daily for up to 10 days or until hospital discharge, whichever comes first, in COVID-19 patients requiring mechanical ventilation and in patients who require supplemental oxygen but who are not mechanically ventilated. Although the clinical benefits of other corticosteroids (e.g., hydrocortisone, methylprednisolone, prednisone) are not clear, the panel recommends using total daily dosages of these drugs equivalent to dexamethasone 6 mg (IV or oral) as follows: Hydrocortisone 160 mg, Methylprednisolone 32 mg, or Prednisone 40 mg. Based on half-life and duration of action, frequency of administration varies among these corticosteroids. Dexamethasone is long-acting and administered once daily. Methylprednisolone and Prednisone are intermediate-acting and administered once daily or in 2 divided doses daily. Hydrocortisone is short-acting and administered in 2-4 divided doses daily. Regimens used in early cases of COVID-19 in China were typically methylprednisolone 40-80 mg IV daily for a course of 3-6 days. Some experts suggest that equivalent dosages of dexamethasone (i.e., 7-15 mg daily, typically 10 mg daily) may have an advantage of producing less fluid retention, since dexamethasone has less mineralocorticoid activity. This dosage of dexamethasone is consistent with those used in the DEXA-ARDS trial. However, lower doses of dexamethasone may be associated with a lower incidence of death.</td>
<td>Data on the use of corticosteroids in COVID-19 are limited. The benefits and risks of corticosteroid therapy should be carefully weighed before use in patients with COVID-19. Non-severe or non-critical patients: Corticosteroids generally should not be used in the treatment of early or mild disease since the drugs can inhibit immune response, reduce pathogen clearance, and increase viral shedding. The WHO Guideline Development Group suggests not using systemic corticosteroids in the treatment of patients with non-severe COVID-19, regardless of hospitalization status. However, if the clinical condition of such non-severe patients worsens (e.g., increased respiratory rate, signs of respiratory distress, or hypoxemia), systemic corticosteroids are recommended for treatment. The WHO Guideline Development Group recommends against discontinuing systemic corticosteroids in patients with non-severe COVID-19 who are receiving systemic corticosteroids for chronic inflammatory conditions.</td>

<td>Dexamethasone</td>
<td></td>
<td></td>
<td>Randomized, controlled, open-label, multicenter study (NCT04327401; CoDEX): This trial was conducted to determine whether IV dexamethasone increases the number of ventilator-free days among patients with COVID-19-associated ARDS. The study enrolled adults with COVID-19 and moderate or severe ARDS who were receiving mechanical ventilation from 41 ICUs in Brazil. In the dexamethasone treatment arm, 151 patients were randomized to receive dexamethasone (20 mg IV once daily for 5 days followed by 10 mg IV once daily for another 5 days or until ICU discharge) plus standard care; 148 patients were randomized to receive standard care alone. The primary study end point was ventilator-free days (defined as number of days alive and free from mechanical ventilation) during the first 28 days. Preliminary data analysis indicates that use of IV dexamethasone plus standard care was associated with a higher mean number of ventilator-free days (6.6 days) compared with those receiving dosages of dexamethasone (i.e., 6 mg once daily for 10 days) were used in the RECOVERY trial. 12,13 Higher dosages of IV Dexamethasone (i.e., 20 mg once daily for 5 days followed by 10 mg once daily for an additional 5 days or until ICU discharge, whichever came first) were used in the CoDEX trial in patients with COVID-19 and moderate or severe ARDS. 39 Continuous IV infusion of Hydrocortisone 200 mg/day for 7 days, followed by 100 mg/day for 4 days, and then 50 mg/day for 3 days (total of 14 days) was used in the CAPE COVID study. If a patient’s respiratory and general status sufficiently improved by day 4, a shorter treatment regimen of Hydrocortisone was used at a dosage of 200 mg/day for 4 days followed by 100 mg/day for 2 days and then 50 mg/day for 2 days (total of 8 days). 40 A fixed dosage of IV Hydrocortisone (50 or 100 mg every 6 hours for 7 days) or a shock-dependent regimen of IV hydrocortisone (50 mg every 6 hours for up to 28 days in the presence of clinically evident shock) was used in the REMAP-CAP study. 41</td>
<td></td>
<td><strong>Severely or critically ill patients:</strong> The Surviving Sepsis Campaign COVID-19 subcommittee (a joint initiative of the Society of Critical Care Medicine and the European Society of Intensive Care Medicine) supports a strong recommendation to use a short course of systemic corticosteroids over not using corticosteroids in adults with severe or critical COVID-19. 52 However, these experts generally support a weak recommendation to use dexamethasone over other systemic corticosteroids when such therapy is considered for the treatment of adults with severe or critical COVID-19. 52 If dexamethasone is not available, these experts state that clinicians may use other systemic corticosteroids at dosages equivalent to dexamethasone 6 mg daily for up to 10 days. 52 Based on findings to date from the RECOVERY trial, the NIH COVID-19 Treatment Guidelines Panel recommends the use of dexamethasone (6 mg daily for up to 10 days or until hospital discharge, whichever comes first) in patients with COVID-19 who are receiving mechanical ventilation or in those who require supplemental oxygen but are not on mechanical ventilation. 24 (See Remdesivir in this Evidence Table for recommendations from the NIH guidelines panel regarding use of dexamethasone with or without remdesivir in COVID-19 patients based on disease severity.) **Based on findings to date from the RECOVERY and REMAP-CAP studies, the NIH COVID-19 Treatment Guidelines Panel recommends the use of dexamethasone with or without remdesivir in hospitalized patients requiring oxygen delivery through a high-flow device or noninvasive ventilation. For such patients who were recently hospitalized with rapidly increasing oxygen needs and systemic inflammation, the panel also...</td>

standard care alone (4 days). Although there was no significant difference in all-cause mortality at 28 days between the treatment groups, the trial was terminated early after results of the RECOVERY trial became available and, therefore, likely underpowered to determine secondary outcomes such as mortality. Dexamethasone was not associated with an increased risk of adverse effects in this study population of critically ill COVID-19 patients.\(^{24,30}\)

**Hydrocortisone randomized, double-blind sequential trial (NCT02517489; CAPE COVID):** This trial was conducted to evaluate the effect of low-dose hydrocortisone compared with placebo on treatment failure in critically ill patients with COVID-19-related acute respiratory failure. The study enrolled adults with COVID-19-associated acute respiratory failure from 9 ICUs in France. In the hydrocortisone treatment arm, 76 patients received a continuous IV infusion of hydrocortisone at an initial dosage of 200 mg/day for 7 days followed by 100 mg/day for 4 days, and then 50 mg/day for 3 days (total of 14 days; some patients received a shorter regimen); 73 patients received placebo. The primary study end point was treatment failure (defined as death or persistent dependency on mechanical ventilation or high-flow oxygen therapy) on day 21. Treatment failure on day 21 occurred in 42.1% of patients in the hydrocortisone group compared with 50.7% of patients in the placebo group. The difference between the treatment groups was not statistically significant; however, the study was discontinued early after results of the RECOVERY trial were announced and, therefore, likely underpowered to determine a statistically and clinically important difference in the primary outcome. \(^{24,40}\)

**Hydrocortisone multicenter, ongoing, international open-label trial using a randomized, embedded multifactorial adaptive platform (NCT02735707; REMAP-CAP):** This trial randomized patients to multiple interventions within multiple domains. In the COVID-19 corticosteroid domain, adults

| Hydrocortisone | | | | | recommends the addition of tocilizumab to either monotherapy with dexamethasone or combination therapy with dexamethasone and remdesivir. The NIH panel also recommends use of dexamethasone plus tocilizumab for hospitalized patients with COVID-19 who are receiving invasive mechanical ventilation or ECMO and who are within 24 hours of ICU admission with rapid respiratory decompensation.\(^{24}\) (See Tocilizumab in this Evidence Table for recommendations from the NIH guidelines panel regarding use of dexamethasone with tocilizumab in COVID-19 patients.) The NIH guidelines panel states that prolonged use of systemic corticosteroids in patients with COVID-19 may increase the risk of reactivation of latent infections (e.g., hepatitis B virus [HBV], herpesvirus, strongyloidiasis, tuberculosis). The risk of reactivation of latent infections following a 10-day course of dexamethasone (6 mg once daily) is not well established. When initiating dexamethasone in patients with COVID-19, appropriate screening and treatment to reduce the risk of *Strongyloides* hyperinfection in those at high risk of strongyloidiasis (e.g., patients from tropical, subtropical, or warm, temperate regions or those engaged in agricultural activities) or fulminant reactivations of HBV should be considered.\(^{24,37,38}\) The NIH guidelines panel also states that it is not known at this time whether other corticosteroids will have a similar benefit as dexamethasone. However, if dexamethasone is not available, the panel recommends using alternative corticosteroids (e.g., hydrocortisone, methylprednisolone, prednisone).\(^{24}\) IDSA suggests the use of dexamethasone over no dexamethasone therapy in hospitalized patients with severe, but noncritical, COVID-19 (i.e., defined as patients with SpO\(_2\) <94% on room air including those who require

| | | | | | |
from 8 countries with suspected or confirmed COVID-19 following admission to an ICU for respiratory or cardiovascular organ support were randomized to receive a fixed 7-day regimen of IV hydrocortisone (50 or 100 mg every 6 hours), a shock-dependent regimen of IV hydrocortisone (50 mg every 6 hours when shock was clinically evident), or no hydrocortisone or other corticosteroid. The primary study end point was organ support-free days (defined as days alive and free of ICU-based respiratory or cardiovascular support) within 21 days. The 7-day fixed regimen and the shock-dependent regimen of hydrocortisone were associated with a 93 and 80% probability of benefit in terms of organ support-free days compared with no hydrocortisone. However, the trial was discontinued early after results of the RECOVERY trial were announced and no treatment strategy met the prespecified criteria for statistical superiority, precluding definitive conclusions. In addition, serious adverse effects were reported in 2.6% of patients in the study (4 patients receiving the fixed-dosage regimen and 5 patients receiving the shock-dependent regimen compared with 1 patient receiving no hydrocortisone).  

Prosp ective meta-analysis of studies using systemic corticosteroids (i.e., dexamethasone, hydrocortisone, or methylprednisolone) from the WHO Rapid Evidence Appraisal for COVID-19 Therapies (REACT) Working Group: This meta-analysis pooled data from 7 randomized clinical trials in 12 countries that evaluated the efficacy of corticosteroids in 1703 critically ill patients with COVID-19. The primary outcome was all-cause mortality up to 30 days after randomization to treatment. Administration of systemic corticosteroids was associated with lower all-cause mortality at 28 days compared with usual care or placebo (222 deaths among 678 patients who received corticosteroids and 425 deaths among 1025 patients who received usual care or placebo). The effect of corticosteroids on reduced mortality was observed in critically ill patients who were and were not receiving mechanical ventilation at randomization and also in patients from the

|         |            |           |                               |        | supplemental oxygen. IDSA recommends the use of dexamethasone over no dexamethasone in hospitalized, critically ill patients with COVID-19 (i.e., defined as patients who are receiving mechanical ventilation or ECMO including those with end organ dysfunction as seen in cases of septic shock or ARDS). These experts suggest the use of dexamethasone 6 mg orally or IV daily for 10 days or until hospital discharge, whichever comes first, or substitution of equivalent daily dosages of other corticosteroids (e.g., methylprednisolone 32 mg, prednisone 40 mg) if dexamethasone is unavailable. However, IDSA suggests against using corticosteroids in hospitalized patients with nonsevere COVID-19 without hypoxemia (i.e., defined as patients with SpO₂ >94% on room air and not requiring supplemental oxygen).  

The WHO Guideline Development Group strongly recommends the use of systemic corticosteroids (e.g., dexamethasone 6 mg orally or IV daily or hydrocortisone 50 mg IV every 8 hours for 7-10 days) over no systemic corticosteroid therapy for the treatment of patients with severe and/or critical COVID-19, regardless of hospitalization status. This treatment recommendation includes critically ill patients with COVID-19 who could not be hospitalized or receive oxygen supplementation because of resource limitations. This treatment recommendation is less clear for populations under-represented in recent clinical trials (e.g., children, patients with tuberculosis, immunocompromised individuals); however, the risk of not using systemic corticosteroids and depriving such patients of potentially life-saving therapy should be considered. The WHO treatment recommendation does not apply to the following uses of corticosteroids: transdermal or inhaled administration, high-dose or long-term dosage regimens, or prophylaxis.  

Cytokine storm: There is no well-established or evidence-based
RECOVERY trial who required supplemental oxygen with or without noninvasive ventilation but who were not receiving invasive mechanical ventilation at the time of randomization. The odds ratios for the association between corticosteroids and mortality were similar for dexamethasone and hydrocortisone. The optimal dosage and duration of corticosteroid treatment could not be determined from this analysis; however, there was no evidence suggesting that a higher dosage of corticosteroids was associated with greater benefit than a lower dosage. The authors also concluded that there was no suggestion of an increased risk of serious adverse effects associated with corticosteroid use. 24, 42

Methylprednisolone randomized, parallel, double-blind, placebo-controlled, phase IIb trial (NCT04343729; Metcovid): This trial was conducted to evaluate the effect of a short course of IV methylprednisolone compared with placebo in hospitalized adults with suspected COVID-19 infection from a single center in Brazil. Patients were enrolled prior to laboratory confirmation of COVID-19 to avoid treatment delays. The presence of COVID-19 was later confirmed based on RT-PCR testing in 81.3% of these patients. 24, 47 At time of enrollment, 34% of patients in each treatment group required invasive mechanical ventilation. Supplemental oxygen was required in 51% of patients receiving methylprednisolone and in 45% of those receiving placebo. 24 In the methylprednisolone treatment arm, 194 patients received IV methylprednisolone at a dosage of 0.5 mg/kg twice daily for 5 days; 199 patients received placebo. A modified intent-to-treat analysis was conducted; the primary study end point was 28-day mortality. Overall, the 28-day mortality rate was 37.1 or 38.2% in patients who received methylprednisolone or placebo, respectively, showing no significant difference in overall mortality between the treatment groups. However, a subgroup analysis found a lower mortality rate in patients >60 years of age who received methylprednisolone compared with placebo (46.6 vs 61.9%, respectively). Patients >60 years of age reportedly had a higher treatment for cytokine storm in patients with COVID-19. 8 However, some experts suggest that use of more potent immunosuppression with corticosteroids may be beneficial in such patients. 3 These experts suggest higher dosages of corticosteroids (e.g., IV methylprednisolone 60-125 mg every 6 hours for up to 3 days) followed by tapering of the dosage when inflammatory markers (e.g., C-reactive protein levels) begin to decrease. 3

Septic shock: The effect of corticosteroids in COVID-19 patients with sepsis or septic shock may be different than the effects seen in those with ARDS. 12 The Surviving Sepsis Campaign and NIH suggest the use of low-dose corticosteroid therapy (e.g., hydrocortisone 200 mg daily as an IV infusion or intermittent doses) over no corticosteroid therapy in adults with COVID-19 and refractory shock. 14, 24 Randomized controlled studies evaluating use of corticosteroids (e.g., hydrocortisone, dexamethasone, methylprednisolone, prednisolone) in septic shock suggest a small, but uncertain mortality reduction. 3, 4 Clinicians considering corticosteroids for such patients with COVID-19 should balance the potential small reduction in mortality with potential effects of prolonged coronavirus shedding. 3 If corticosteroids are prescribed, monitor and treat adverse effects including hyperglycemia, hypernatremia, and hypokalemia. 1, 4

Patients receiving corticosteroid therapy for chronic conditions: NIH states that oral corticosteroids used for the treatment of an underlying condition prior to COVID-19 infection (e.g., primary or secondary adrenal insufficiency, rheumatologic diseases) should not be discontinued in patients with COVID-19 unless discontinuation is otherwise warranted by their clinical condition. Supplemental or stress dosages of corticosteroids may be indicated on an individual basis in patients with such conditions. 24 (See Corticosteroids [inhaled] in...

<td></td>
<td></td>
<td>Endocrinology experts state that patients with primary or secondary adrenal insufficiency who are receiving prolonged corticosteroid therapy should follow usual steroid “sick day rules” since these individuals may not be able to mount a normal stress response in the event of COVID-19 infection. If such individuals develop symptoms such as fever and a dry continuous cough, they should immediately double their daily oral corticosteroid dosage and continue with this regimen until the fever subsides. These guidelines also apply to patients who are receiving prolonged therapy (&gt; 3 months) with corticosteroids for underlying inflammatory conditions, including asthma, allergy, and rheumatoid arthritis. In such patients whose condition worsens or in those experiencing vomiting or diarrhea, treatment with parenteral corticosteroids may be necessary. Administration of physiologic stress doses of corticosteroids (e.g., IV hydrocortisone 50-100 mg 3 times daily) and not pharmacologic doses should be considered in all cases to avoid potentially fatal adrenal failure. Additional study is needed to determine the optimum corticosteroid stress dosage regimens in</td>

</table>
Therefore, use of methylprednisolone was associated with a reduction in the risk of ICU admission, invasive mechanical ventilation, or death within 28 days (adjusted hazard ratio: 0.41). Specifically, 18.1 or 30% of patients required ICU admission and 16.9 or 28.9% of patients required invasive mechanical ventilation in those receiving methylprednisolone or standard care alone, respectively. In addition, use of methylprednisolone was associated with a 28-day lower risk of all-cause mortality than use of standard care alone (7.2 vs 23.3%, respectively) with an adjusted hazard ratio of 0.29. Overall, there was no difference in adverse effects between treatment groups with the exception of increased reports of hyperglycemia and mild agitation in the methylprednisolone-treated patients; no adverse effects resulted in drug discontinuation. The authors concluded that early, low-dose, prolonged therapy with methylprednisolone resulted in decreased ICU burden, reduced duration for invasive mechanical ventilation, and lower mortality along with improvement in systemic inflammation and oxygenation markers in hospitalized patients with severe COVID-19 pneumonia at high risk of progression to acute respiratory failure. 48

**Retrospective, case-control study using systemic corticosteroids (i.e., methylprednisolone, prednisone):** This trial was conducted to evaluate the efficacy of early, low-dose, short-term therapy with systemic methylprednisolone or prednisone in hospitalized adults from a single center in China with non-severe COVID-19 pneumonia. A total of 475 patients were enrolled with 55 of these patients receiving early, low-dose corticosteroids. Methylprednisolone 20 or 40 mg IV daily was administered to 50 of these patients for 3-5 days, and oral prednisone 20 mg daily (equivalent dosage to methylprednisolone) was administered to 5 such patients for 3 days. Corticosteroid therapy was initiated within a median of 2 days following hospital admission. A total of 420 patients received standard therapy (no corticosteroids); using propensity score matching, 55 of these patients were selected as matched controls. The primary outcome was the rate of patients who

</table>

patients with COVID-19. 26, 27 There is some evidence suggesting that continuous IV infusion of hydrocortisone (following an initial IV bolus dose) may provide more stable circulating cortisol concentrations in patients with adrenal insufficiency and reduce the potentially harmful effects of peak and trough concentrations of cortisol on the immune system. 26, 27

**Pregnancy:** For pregnant women with COVID-19, the NIH COVID-19 Treatment Guidelines Panel states that a short course of corticosteroids that cross the placenta (i.e., betamethasone, dexamethasone) is routinely used for fetal benefit (e.g., to hasten fetal lung maturity). Given the potential benefit of decreased maternal mortality and the low risk of fetal adverse effects for this short course of corticosteroid therapy, the panel recommends the use of dexamethasone in pregnant women with COVID-19 who are receiving mechanical ventilation or in those who require supplemental oxygen but are not on mechanical ventilation. 24

The WHO Guideline Development Group recommends antenatal corticosteroid therapy for pregnant women at risk of preterm birth from 24-34 weeks’ gestation when there is no clinical evidence of maternal infection and adequate maternal and newborn care are available. In cases where a pregnant woman presents with mild or moderate COVID-19, the clinical benefits of antenatal corticosteroids may outweigh the risk of potential harm to the woman. The balance of benefits and risks for the woman and preterm infant should be considered during the informed decision-making process. 43

**Pediatric use:** The safety and efficacy of dexamethasone or other corticosteroids for COVID-19 treatment have not been sufficiently evaluated in pediatric patients. Therefore, caution is warranted when extrapolating recommendations for adults to patients <18 years of age. Importantly, the
developed severe disease and mortality. In the corticosteroid treatment arm, 12.7% of patients developed severe disease compared with 1.8% of patients in the control group. There was one death in the group receiving methylprednisolone and none in the control group. Regarding secondary outcomes, duration of fever, virus clearance time, and length of hospital stay were all significantly longer in patients receiving corticosteroids compared with no corticosteroid therapy. Because of the finding that early, low-dose, short-term systemic corticosteroid therapy was associated with worse clinical outcomes in hospitalized adult patients with non-severe COVID-19 pneumonia, the authors concluded that the study results do not support the use of corticosteroids in this population. However, it is difficult to interpret these results because of potential confounding factors inherent in the nonrandomized study design. It is unclear if the results of this study apply to corticosteroids other than methylprednisolone.

Methylprednisolone multicenter quasi-experimental study with single pretest and posttest (NCT04374071): This trial was conducted to evaluate the efficacy of early, short-term therapy with systemic methylprednisolone in hospitalized adults with confirmed moderate to severe COVID-19 from a multicenter health system in Michigan. A total of 213 patients were enrolled with 132 patients receiving early therapy with IV methylprednisolone at dosages of 0.5–1 mg/kg daily in 2 divided doses for 3 days plus standard care and 81 patients receiving early therapy with standard care alone. The primary end point was a composite based on the need for ICU transfer, progression to respiratory failure requiring mechanical ventilation, or inhospital all-cause mortality. The primary composite end point occurred at a significantly lower rate in the group receiving early corticosteroid therapy (34.9%) compared with the group receiving early therapy with standard care alone (54.3%). The early corticosteroid group had a median time to initiation of methylprednisolone of 2 days compared with 5 days for the RECOVERY trial did not include a significant number of pediatric patients, and mortality rates are significantly lower for pediatric patients with COVID-19 than for adult patients with the disease. Therefore, results of this trial should be interpreted with caution for patients <18 years of age. The NIH COVID-19 Treatment Guidelines Panel recommends use of dexamethasone for hospitalized pediatric patients with COVID-19 who are receiving high-flow oxygen, noninvasive ventilation, invasive mechanical ventilation, or ECMO. Dexamethasone is generally not recommended for pediatric patients who require only low levels of oxygen support (i.e., nasal cannula only). For pediatric patients with COVID-19, the NIH panel recommends dexamethasone at a dosage of 0.15 mg/kg (maximum dose 6 mg) once daily for up to 10 days. If dexamethasone is not available, alternative corticosteroids such as hydrocortisone, methylprednisolone, or prednisone may be considered. Additional studies are needed to evaluate the use of corticosteroids for the treatment of COVID-19 in pediatric patients, including in those with multisystem inflammatory syndrome in children (MIS-C). Although immune globulin IV (IGIV) and/or corticosteroids generally have been used as first-line therapy in pediatric patients with MIS-C, the NIH COVID-19 Treatment Guidelines Panel recommends consultation with a multidisciplinary team when considering and managing immunomodulating therapy for children with this condition. The optimal choice and combination of immunomodulating therapies for children with MIS-C have not been definitely established.
standard care group. The median hospital length of stay was significantly reduced from 8 to 5 days in patients receiving early corticosteroid therapy compared with those receiving early therapy with standard care alone. ARDS occurred in 26.6% of patients receiving early corticosteroid therapy compared with 38.3% of those in the standard care group. The authors concluded that early, short-term therapy with methylprednisolone in patients with moderate to severe COVID-19 may prevent disease progression and improve clinical outcomes.

**Note:** Limitations of this study include the following: differences were noted in the baseline characteristics of the comparator groups; some patients in the standard care group received corticosteroids, but initiation of therapy was significantly later than in the early corticosteroid group; and patient follow-up for both treatment groups was limited to 14 days.  

**Methylprednisolone open-label, multicenter, randomized, controlled study (NCT04244591):** This recently completed trial compared use of methylprednisolone in conjunction with standard care in patients with confirmed COVID-19 infection that progressed to acute respiratory failure; results have not yet been posted.  

**Retrospective, observational study of systemic corticosteroid use in patients with COVID-19 from a New York hospital (Keller et al):** Data are available for 1806 patients hospitalized with COVID-19 between Mar 11 and Apr 13, 2020. Patients included in the analysis were those treated with systemic corticosteroids (e.g., dexamethasone, hydrocortisone, methylprednisolone, prednisone) within the first 48 hours of hospital admission (140 patients) and those not treated with corticosteroids (1666 patients) as the control group. Treatment and control groups were similar except that corticosteroid-treated patients were more likely to have a history of COPD, asthma, rheumatoid arthritis, or lupus, or to have received corticosteroids in the year prior to admission. Primary goal of the study was to determine whether early systemic corticosteroid treatment was associated with...
reduced mortality or need for mechanical ventilation. Overall, early use of systemic corticosteroids was not associated with in-hospital mortality or mechanical ventilation. However, there was a significant treatment effect based on C-reactive protein (CRP) levels. Early use of corticosteroids in patients with initial CRP levels of ≥20 mg/dL was associated with a significantly reduced risk of mortality or need for mechanical ventilation (odds ratio: 0.23). Conversely, such treatment in patients with initial CRP levels of <10 mg/dL was associated with a significantly increased risk of mortality or need for mechanical ventilation (odds ratio: 2.64). The authors state that these findings suggest that appropriate selection of COVID-19 patients for systemic corticosteroid treatment is critical to maximize the likelihood of benefit and minimize the risk of harm. Note: The limitations of the observational study design should be considered when interpreting these results. Corticosteroid dosages used in patients included in this study not provided. Further study is needed to determine the role of CRP levels in guiding the use of corticosteroid treatment in patients with COVID-19. 36

**Retrospective study of systemic corticosteroids and/or other immunosuppressive therapies and their effect on COVID-19 infection in patients with chronic immune-mediated inflammatory arthritis (Favalli et al):** This study evaluated the frequency and characteristics of symptomatic COVID-19 infection in relation to use of different immunosuppressive agents in such patients. Data are available from a cross-sectional survey administered to 2050 adults receiving follow-up care at arthritis outpatient clinics of 2 large academic hospitals in Italy. Patients surveyed had arthritis of long duration (median of 10 years) and 62% were receiving therapy with biologic or targeted synthetic disease-modifying antirheumatic drugs (DMARDs) alone or in combination with conventional synthetic DMARDs; approximately one-third of these patients were also receiving concomitant long-term treatment with systemic corticosteroids. Laboratory-confirmed COVID-19 or highly
suspected infection (based on close contact with a confirmed COVID-19 case within 14 days prior to onset of symptoms) was reported in 1.1 or 1.4% of patients, respectively. In this study, corticosteroid treatment was independently associated with an increased risk of COVID-19 infection, especially at prednisone dosages ≥ 2.5 mg daily. The use of corticosteroids was confirmed to independently predict increased risk of COVID-19 infection regardless of comorbidities, precautions taken to prevent infection, and contacts with COVID-19 cases. Conversely, treatment with biologic/targeted synthetic DMARDs was associated with a reduced risk of COVID-19 infection. Limitations of this study include its retrospective nature and the definition of COVID-19 cases based on patient survey results. The authors state these data should not result in indiscriminate discontinuance of systemic corticosteroids in patients with chronic immune-mediated inflammatory arthritis, but underscore the importance of a benefit-risk assessment in individual patients.50

</table>
evidence of benefit or harm with routine use of inhaled corticosteroids on COVID-19-related mortality among individuals with COPD or asthma. 44, 45

**Phase 2, randomized, controlled, open-label, parallel group study (not peer-reviewed) evaluating the use of inhaled budesonide in adults with early COVID-19 (NCT04416399; STOIC):** This trial was conducted to evaluate the use of inhaled budesonide compared with usual care in 146 nonhospitalized adults from the UK with early symptoms suggestive of COVID-19. COVID-19 infection was later confirmed by RT-PCR in 94% of these patients. Prior to randomization, the median duration of symptoms was 3 days. Total of 70 patients were randomized to receive inhaled budesonide as a dry powder inhaler at a dosage of 800 mcg twice daily and 69 patients were randomized to receive usual care, with a total of 139 patients included in the per-protocol analysis. In the budesonide group, the drug was administered for a median duration of 7 days. The primary end point was defined as an urgent care visit, emergency department assessment, or hospitalization. This outcome occurred in 10 patients from the usual care group compared with 1 patient from the budesonide group. In addition, fewer patients receiving inhaled budesonide had persistent symptoms at days 14 and 28 compared with those receiving usual care. Study results suggest that early administration of inhaled budesonide reduces the likelihood of needing urgent medical care, emergency department consultation, or hospitalization in patients with early COVID-19 illness. Use of inhaled budesonide was also associated with self-reported reduced time to symptom resolution from COVID-19 infection. 53

*** Multicenter, randomized, controlled, open-label, adaptive platform study (not peer reviewed) evaluating the use of inhaled budesonide in adults in the community with suspected COVID-19 at higher risk of adverse outcomes (PRINCIPLE):** This trial compared the use of standard care alone, standard care plus inhaled...
budesonide, or standard care plus other interventions in nonhospitalized adults in the UK who had suspected COVID-19 and were ≥65 years of age or ≥50 years of age with comorbidities. COVID-19 infection was later confirmed in 2617 (56%) of these patients, of which 2422 had follow-up data and, therefore, were included in the primary analysis. Patients were randomized to receive standard care alone (n=1028), standard care plus inhaled budesonide at a dosage of 800 mcg twice daily for 14 days (n=751), or standard care plus other interventions (n=643). The coprimary end points were time to first self-reported recovery and COVID-19-related hospitalization or death (both end points measured within 28 days after randomization). Inhaled budesonide appeared to reduce time to recovery by a median of 3 days in adults with COVID-19 who had comorbidities that put them at higher risk for complications. Among patients in the inhaled budesonide group who had 28 days of follow-up data, a lower rate of COVID-19-related hospitalization or death was observed compared with patients in the standard care group (8.5 versus 10.3%, respectively). Final data analysis is pending completion of 28-day follow-up for all patients randomized to receive inhaled budesonide.54

A small case series from Japan observed possible clinical benefit in 3 patients with mild to moderate COVID-19 pneumonia following oral inhalation of ciclesonide; however, without a control group, it is not known whether the patients would have improved spontaneously.35

Various clinical trials evaluating the use of inhaled corticosteroids (e.g., budesonide, ciclesonide) in patients with COVID-19 are registered at clinicaltrials.gov.22

In patients with ARDS, various dosages of inhaled epoprostenol have been used; dosages up to 50 ng/kg per minute (titrated to response) have been used in clinical studies.1-4,6,9

The Surviving Sepsis Campaign states that due to the lack of adequately powered randomized controlled studies, a recommendation cannot be made for or against the use of inhaled prostacyclins in COVID-19 patients with severe ARDS.10

<td>Interferons</td>
<td>8:18.20 Interferons 10:00 Antineoplastic Agents 92:20 Immunomodulatory Agents</td>
<td>Interferons (IFNs) modulate immune responses to some viral infections. In vitro studies indicate only weak induction of IFN following SARS-CoV-2 infection, and a possible role for IFNs in prophylaxis or early treatment of COVID-19 has been suggested to compensate for possibly insufficient endogenous IFN production.</td>
<td>Only limited clinical trial data available to date specifically evaluating efficacy of IFNs for treatment of COVID-19; for information on additional studies including IFN alfa or IFN beta as a component of combination therapy (e.g., background regimen), see antiviral entries in this Evidence Table. Various clinical trials evaluating IFN beta-1a, IFN beta-1b, or peginterferon [pegIFN] beta-1a, generally added to other antivirals, for treatment of COVID-19 are registered at clinicaltrials.gov. PegIFN beta-1a also is being evaluated for postexposure prophylaxis of SARS-CoV-2 infection.</td>
<td>IFN beta: Various sub-Q dosages of IFN beta-1a and IFN beta-1b are being evaluated for treatment of COVID-19.</td>
<td>Efficacy and safety of IFNs for treatment or prevention of COVID-19 not established. Relative effectiveness of different IFNs against SARS-CoV-2 not established. NIH COVID-19 Treatment Guidelines Panel recommends against use of IFNs for treatment of severe or critical COVID-19, except in the context of a clinical trial. The panel also states there are insufficient data to recommend either for or against use of IFN beta for the treatment of early (i.e., &lt;7 days from [\text{PaO}_2/FiO}_2] by &gt;10%), there were no significant changes in other oxygenation parameters or clinical outcomes. In another retrospective observational study in 80 mechanically ventilated COVID-19 patients, clinically significant improvement in [\text{PaO}_2/FiO}_2] (defined as an increase by 10% from baseline values) was observed in 50% of the patients following treatment with inhaled epoprostenol (initial dose of 50 ng/kg per minute delivered through the ventilator tubing); however, the benefit was generally modest and there was wide variability in response. Numerous limitations of the observational studies described above preclude definitive conclusions. Inhaled prostanclins may be included in some COVID-19 clinical trials registered at clinicaltrials.gov.</td>

### Drug(s) | AHFS Class | Rationale | Trials or Clinical Experience | Dosage | Comments
--- | --- | --- | --- | --- | ---
Type 1 IFNs (IFN alfa and IFN beta) are active in vitro against MERS-CoV in Vero and LLC-MK2 cells and in rhesus macaque model of MERS-CoV infection; type 1 IFNs also active in vitro against SARS-CoV-1 in Vero, iRiHK-4, and human cell lines. IFN beta is more active than IFN alfa in vitro against SARS-CoV-1 and MERS-CoV.\(^2, 8, 12\)

IFN alfa and IFN beta are active in vitro against SARS-CoV-2 in Vero cells at clinically relevant concentrations; in vitro study suggests SARS-CoV-2 is more sensitive than SARS-CoV-1 to IFN alfa.\(^1,3\)

However, lack of clinical benefit observed with use of type 1 IFNs, generally in combination with ribavirin, for treatment of SARS and MERS.\(^2, 8, 9, 11, 12\)

IV IFN beta-1a did not reduce ventilator dependence or mortality in a placebo-controlled trial in patients with acute respiratory distress syndrome (ARDS).\(^11, 17\)

Type 3 IFNs (IFN lambda) are thought to provide important immunologic defense against respiratory viral infections and may have less potential than type 1 IFNs to produce systemic inflammatory response, including inflammatory effects on respiratory tract.\(^3, 4, 6, 7, 15\)

IFN lambda receptor is expressed mainly on epithelial (including respiratory epithelial) cells and

**Open-label, randomized study in Hong Kong in hospitalized adults with COVID-19, mainly mild disease (NCT04276688):** Combination regimen of LPV/RTV, ribavirin, and sub-Q IFN beta-1b (IFN beta-1b was omitted to avoid proinflammatory effects when treatment was initiated 7-14 days after symptom onset) was associated with shorter median time from treatment initiation to negative RT-PCR result in nasopharyngeal swab (7 vs 12 days), earlier resolution of symptoms (4 vs 8 days), and shorter hospital stay (9 vs 14.5 days) compared with control (LPV/RTV). In the subset of patients initiating treatment 7 or more days after symptom onset (i.e., those not treated with IFN beta-1b), there was no significant difference in time to negative RT-PCR result, time to resolution of symptoms, or duration of hospital stay between the combination regimen (LPV/RTV and ribavirin) and control (LPV/RTV). IFN beta-1b (8 million units on alternate days) was administered for 1, 2, or 3 doses when initiated on day 5-6, 3-4, or 1-2, respectively, following symptom onset (median of 2 IFN beta-1b doses given); 52 of 86 patients (60%) randomized to combination regimen received all 3 drugs, and 41 patients received control LPV/RTV.\(^10\)

**Open-label, randomized study in hospitalized adults with severe COVID-19: Regimen of IFN beta-1b (250 mcg sub-Q every other day for 2 weeks) plus Iran national protocol medications was compared with national protocol alone (control). Protocol included a 7- to 10-day regimen of lopinavir/ritonavir or atazanavir/ritonavir and hydroxychloroquine. All patients required respiratory support (mainly oxygenation through facemask [80%]) but none were intubated at baseline. Median time from symptom onset to randomization was 8 days. Total of 80 patients were randomized (40 to each treatment group); analyses were based on data for 33 patients per treatment group after exclusion of those who withdrew consent, were enrolled in another study, or received <4 IFN doses. Median time to clinical improvement (defined as ≥2-category improvement in a 6-category ordinal scale) was shorter in the treatment group after exclusion of those who withdrew consent, were enrolled in another study, or received <4 IFN doses. Median time to clinical improvement (defined as ≥2-category improvement in a 6-category ordinal scale) was shorter in the**

**Open-label, randomized study in hospitalized adults with COVID-19, mainly mild disease (NCT04276688):** IFN beta-1b 8 million units was given sub-Q on alternate days for 1, 2, or 3 doses (when initiated on day 5-6, 3-4, or 1-2, respectively, following symptom onset) in conjunction with 14-day regimen of LPV/RTV and ribavirin.\(^25, 26\)

In an open-label, randomized study in hospitalized adults with severe COVID-19, IFN beta-1b 250 mcg was given sub-Q every other day for 2 weeks.\(^25\)

In the SOLIDARITY study, most IFN-treated patients received three 44-mcg doses of IFN beta-1a sub-Q over 6 days.\(^23\)

In an open-label, randomized study in hospitalized adults with severe COVID-19, IFN beta-1a 12 million units was given sub-Q 3 times weekly for 10 days for treatment of COVID-19.\(^13\)

IFN alfa: National guidelines from China suggest IFN alfa dosage of 5 million units (or equivalent) twice daily via inhalation for up to 10 days for treatment of COVID-19.\(^13\)

PegIFN lambda-1a:

For treatment of COVID-19 in adults (NCT04354259): a single 180-mcg sub-Q dose of pegIFN lambda-1a was given.\(^32\)

For postexposure prophylaxis of CoV-2 infection in adults (NCT04344600): Two 180-mcg sub-Q doses of peginterferon lambda-1a given 1 week apart.\(^13\)
neutrophils, and is distinct from the ubiquitous type 1 IFN receptor;\(^2, 4, 7, 19\) despite different receptors and expression patterns, type 1 and type 3 IFNs activate similar signaling cascades;\(^4, 7, 19\) unknown whether limited receptor distribution might also affect efficacy\(^4\)

**Open-label, randomized study in** Iran in hospitalized adults with severe suspected or RT-PCR-confirmed COVID-19: **IFN beta-1a** (12 million units sub-Q 3 times weekly for 2 weeks) plus standard care (7- to 10-day regimen of hydroxychloroquine plus lopinavir/ritonavir or atazanavir/ritonavir) \((n = 42)\) was compared with standard care (control; \(n = 39)\). Time to clinical response (primary outcome; defined as hospital discharge or 2-score improvement in a 6-category ordinal scale) did not differ significantly between the IFN beta-1a group and the control group (9.7 vs 8.3 days); durations of hospital stay, ICU stay, and mechanical ventilation also did not differ between the groups. Discharge rate on day 14 (67% vs 44%) was higher and 28-day overall mortality rate (19 vs 44%) was significantly lower with IFN beta-1a compared with control; early initiation of IFN beta-1a (<10 days after symptom onset), but not late initiation of the drug (≥10 days after symptom onset), was associated with reduced mortality. **NOTE:** Total of 92 patients were randomized; results are based on the 42 IFN beta-1a-treated patients and 39 control patients who completed the study. Diagnosis of COVID-19 was based on RT-PCR testing (64%) or clinical manifestations/imaging findings (36%). Other concomitant therapies included corticosteroids and immune globulin (IFN beta-1a group: 62 and 36%, respectively; control group: 44 and 26%, respectively). Patients were recruited from general, intermediate, and ICU wards; 45% of the IFN beta-1a-treated patients and 59% of the control patients were admitted to ICU; 36 and 44%, respectively, required invasive mechanical ventilation. Mean time from symptom onset to treatment initiation was 11.7 days for the IFN beta-1a group and 9.3 days for the control group.\(^20\)
Large, multinational, open-label, randomized, adaptive trial launched by the World Health Organization (WHO) to evaluate effects of 4 different treatments compared with local standard of care in adults hospitalized with COVID-19 and not previously treated with any of the study drugs (SOLIDARITY; NCT04315948): The protocol-specified primary outcome is in-hospital mortality; protocol-specified secondary outcomes are initiation of ventilation and duration of hospitalization. **Interim results have been reported, including results for the IFN beta-1a treatment arm.** From March 22 to October 4, 2020, 2063 patients were randomized to receive IFN (given in conjunction with lopinavir and ritonavir \([n = 651]\) or standard of care \([n = 1412]\)) and 2064 patients were randomized to IFN control (either lopinavir and ritonavir or standard of care, for the respective IFN regimens). Most IFN-treated patients received three 44-mcg doses of IFN beta-1a sub-Q over 6 days; where IV IFN was available, patients on high-flow oxygen, ventilators, or ECMO received 10 mcg IV once daily for 6 days. Preliminary data analysis for the intention-to-treat (ITT) population indicated that IFN did not reduce in-hospital mortality (either overall or in any subgroup defined by age or ventilation status at study entry) and did not reduce the need for initiation of ventilation or the duration of hospitalization. The log-rank death rate ratio for IFN in the ITT population was 1.16; 243/2050 patients treated with IFN (12.9%) and 216/2050 control patients (11%) died. About one-half of the patients randomized to receive IFN or IFN control received corticosteroids; this did not appear to affect the death rate ratio. The clinical relevance of the difference in the pharmacokinetic profiles of sub-Q and IV IFN is unclear. 23, 28

Phase 2, randomized, double-blind, multicenter, placebo-controlled study (NCT04385095; SG016) evaluating SNG001 (inhaled IFN beta-1a) in adults with COVID-19: In the in-hospital portion of the study, patients received SNG001 (IFN beta-1a 6 million units via nebulizer once daily for up to 14 days) plus standard care or placebo.
plus standard care. The intention-to-treat population for the interim analysis included 48 patients treated with SNG001 and 50 patients given placebo. More patients in the SNG001 group had hypertension (69 vs 41%) and received oxygen at baseline (77 vs 58%), while more patients in the control group had diabetes mellitus (33 vs 12%) or cardiovascular disease (30 vs 19%). Median duration of symptoms before initiation of treatment was 10 days. Clinical outcomes were assessed on the WHO ordinal scale for clinical improvement; statistical models were adjusted for baseline and demographic factors. Hazard ratio for time to recovery (2.19) during the 14-day treatment period and odds ratios for recovery (3.19) and for improvement (2.32) on day 15 or 16 favored SNG001 over placebo. The study has been extended to include 120 patients in the home setting.  

**Aerosolized IFN alfa** (not commercially available in U.S.) has been used in China in children and adults for treatment of COVID-19, but limited clinical data presented to date. In a retrospective study of 77 hospitalized adults with moderate COVID-19 disease who received aerosolized IFN alfa-2b (5 million units twice daily) (n = 7), umifenovir (Arbidol®) (n = 24), or both drugs (n = 46), time from symptom onset to negative RT-PCR result in throat swab appeared to be shorter in those receiving IFN alfa-2b alone or in combination with umifenovir compared with those receiving umifenovir alone; this exploratory study was small and nonrandomized, and treatment groups were of unequal size and demographically unbalanced in age, comorbidities, and time from symptom onset to treatment.  

**Retrospective cohort study** in 446 hospitalized patients who received antiviral therapy for COVID-19 suggested that early IFN alfa-2b therapy (within first 5 days of hospitalization) was associated with reduced in-hospital mortality while late IFN alfa-2b therapy was associated with increased mortality and delayed recovery. In this study, 48.4% of patients received early IFN therapy, 6% received late IFN therapy, and
46% received no IFN. Median time from symptom onset to admission was 6 days, and median time from admission to first IFN dose was 2 or 8.5 days in the early or late IFN group, respectively. Median duration of IFN therapy was 10 or 8.5 days in the early or late IFN group, respectively.  

Preliminary, retrospective, single-center, matched case-control study in 104 patients hospitalized with COVID-19 suggested that IFN alfa-2b therapy (100,000 units by inhalation 4 times daily for 7 days) did not reduce the duration of viral shedding. Duration of viral shedding (based on 2 consecutive negative RT-PCR results) was not significantly different between the matched-pair groups (12 days in 32 IFN-treated patients vs 15 days in 32 control patients [no IFN treatment]).

Randomized, double-blind, placebo-controlled trial (NCT04354259) in 60 adults with confirmed SARS-CoV-2 infection: Patients who received pegIFN lambda-1a (single 180-mcg sub-Q injection) within 7 days of symptom onset or first positive nasal swab test (if asymptomatic) had greater reduction in viral load compared with those receiving placebo. By day 7 after treatment, 80% of pegIFN lambda-1a recipients and 63% of placebo recipients had undetectable SARS-CoV-2 RNA. After controlling for a higher baseline viral load in the pegIFN lambda-1a group compared with the placebo group (6.16 vs 4.87 log10 copies/mL; 5 vs 10 patients in these respective groups had undetectable SARS-CoV-2 RNA on day of randomization), patients in the pegIFN lambda-1a group were more likely to have undetectable viral RNA by day 7 after treatment (odds ratio 4.12; 95% CI 1.15-16.73). At low viral loads, viral clearance tended to occur rapidly regardless of treatment assignment. Studies establishing clinical benefit (e.g., effects on morbidity, mortality, or virus transmission) still required.

Other trials evaluating sub-Q pegIFN lambda-1a (not commercially available in U.S.) for treatment or postexposure prophylaxis of SARS-CoV-2 infection are registered at clinicaltrials.gov.

<td>Nitric oxide (inhaled)</td>
<td>48:48 Vasodilating Agent</td>
<td>Selective pulmonary vasodilator with bronchodilatory and vasodilatory effects in addition to other systemic effects mediated through cGMP-dependent or independent mechanisms; may be useful for supportive treatment of acute respiratory distress syndrome (ARDS), a complication of COVID-19&lt;sup&gt;1, 2, 3, 9, 11, 14&lt;/sup&gt;</td>
<td>The available evidence indicates that inhaled nitric oxide can modestly improve oxygenation in patients with ARDS, but has no mortality benefit and may cause possible harm (e.g., renal impairment).&lt;sup&gt;4, 6, 9&lt;/sup&gt; It is not clear whether or how COVID-19-associated ARDS differs from ARDS related to other etiologies.&lt;sup&gt;18, 20&lt;/sup&gt; Evidence supporting the use of inhaled nitric oxide in COVID-19 patients is currently limited.&lt;sup&gt;15, 16&lt;/sup&gt; Various case reports, case series, and observational studies have described the use of inhaled nitric oxide in mechanically ventilated patients with COVID-19.&lt;sup&gt;13, 15, 16&lt;/sup&gt; Findings generally have been inconsistent, with some improvement in oxygenation reported in some studies and minimal to no improvement in others; various dosages of inhaled nitric oxide were used and patients were receiving other therapies confounding interpretation of the data. In a small cohort (n=6) of pregnant women with hypoxic respiratory failure secondary to COVID-19, intermittent twice-daily treatments with high-dose inhaled nitric oxide (160-200 ppm for 30 minutes to 1 hour administered to spontaneously breathing patients using a mask) improved systemic oxygenation. The decision to use a high dose of inhaled nitric oxide was based on prior reports showing broad antimicrobial effects of such high doses. However, fetal parameters and the development of acute kidney injury (a known complication of nitric oxide therapy) were not monitored.&lt;sup&gt;19&lt;/sup&gt; Results of a retrospective, single-center, observational study in intubated patients with COVID-19 and refractory hypoxemia did not show significant improvement in oxygenation metrics following treatment with inhaled epoprostenol or inhaled nitric oxide. In this study, 38 patients initially received inhaled epoprostenol (starting dose of 0.05 mcg/kg per minute, continued based on PaO&lt;sub&gt;2&lt;/sub&gt; response); 11 patients who did not respond to epoprostenol were transitioned to inhaled nitric oxide (starting dose of 20 ppm, titrated up to 80 ppm based on PaO&lt;sub&gt;2&lt;/sub&gt; response). Although 42.1%</td>
<td>In the Chen et al. study in severe SARS patients, inhaled nitric oxide therapy was given for ≥3 days (30 ppm on day 1, followed by 20 and 10 ppm on days 2 and 3, respectively, then weaned on day 4; therapy was resumed at 10 ppm if deteriorating oxygenation occurred).&lt;sup&gt;2&lt;/sup&gt; Dosages of inhaled nitric oxide used in patients with COVID-19 have varied. (See Trials or Clinical Experience.)</td>
<td>The NIH COVID-19 Treatment Guidelines Panel and the Surviving Sepsis Campaign recommend against the routine use of inhaled nitric oxide in mechanically ventilated adults with COVID-19 and ARDS.&lt;sup&gt;10, 12&lt;/sup&gt; These experts state that a trial of inhaled pulmonary vasodilator may be considered as rescue therapy in mechanically ventilated adults with COVID-19, severe ARDS, and hypoxemia; however, if no rapid improvement in oxygenation is observed, the patient should be tapered off treatment.&lt;sup&gt;10, 12&lt;/sup&gt;</td>
</tr>
</tbody>
</table>

<sup>a</sup>See Trials or Clinical Experience.
of patients who received epoprostenol and 63.6% of patients who received nitric oxide were considered responders (defined as an increase in PaO$_2$/FiO$_2$ by >10%), there were no significant changes in other oxygenation parameters or clinical outcomes. Limitations of the study include its retrospective nature and small sample size. 

In a report describing administration of inhaled nitric oxide (initial dose 30 ppm; mean duration of therapy 2.1 days) to 39 spontaneously breathing patients with laboratory-confirmed COVID-19 (29 were initially admitted to the general medical floor and 24 of these patients later required transfer to the ICU), approximately half of the patients did not require invasive mechanical ventilation after treatment. These findings suggest a role of inhaled nitric oxide in preventing progression of hypoxic respiratory failure; however, randomized controlled studies are needed. 

In a single-center prospective study, 34 critically ill adults with COVID-19 received inhaled nitric oxide (10 ppm administered through the inspiratory limb of the ventilator tubing when PaO$_2$/FiO$_2$ <150). A response (defined as improvement in PaO$_2$/FiO$_2$ of >20% during the 30 minutes following administration) was achieved in 65% of the patients. 

Nitric oxide may be included in some COVID-19 clinical trials registered at clinicaltrials.gov.

### Ruxolitinib (Jakafi®)

</tbody>
</table>
antimicrobials (77%), antivirals (62%), and corticosteroids (29%). Cumulative incidence of clinical improvement (decrease of ≥2 categories on a 7-category ordinal scale within 28 days) was 82%; overall survival at day 28 was 94%. Clinical improvement was not affected by low-flow versus high-flow oxygen support but was less frequent in patients with PaO$_2$/FiO$_2$ ratio <200. 17

Compassionate use of ruxolitinib in combination with eculizumab (a terminal complement inhibitor) in adults with RT-PCR-confirmed COVID-19 and associated pneumonia or acute respiratory distress syndrome (ARDS) in Italy: Consecutive patients received ruxolitinib (10 mg twice daily for 14 days) and eculizumab (900 mg IV once weekly for 2 or 3 doses) (n = 7) or best available therapy (n = 10; control). Greater improvement in median PaO$_2$ and PaO$_2$/FiO$_2$ ratio and greater increase in platelet count observed on day 7 in patients receiving ruxolitinib and eculizumab compared with control patients. All patients received antibiotic prophylaxis (azithromycin) and all patients except 2 in control group received hydroxychloroquine; greater proportion of patients in the ruxolitinib and eculizumab group compared with the control group received low-dose corticosteroids (5/7 vs 3/10) and sub-Q heparin (7/7 vs 5/10). Randomized, controlled trials needed to confirm these preliminary data. 15

Small retrospective cohort study of adults with RT-PCR-confirmed COVID-19 and associated ARDS: Total of 18 patients with PaO$_2$/FiO$_2$ ratio of 100 to <200 and rapid clinical worsening of respiratory function received ruxolitinib (20 mg twice daily for initial 48 hours, with subsequent stepwise dosage reductions based on response, for a maximum of 14 days of treatment); ruxolitinib was initiated at a median of 9 days after symptom onset. Other therapies were used according to local practice. Clinical improvements in respiratory function within 48 hours and avoidance of mechanical ventilation reported in 16 patients; spontaneous breathing with pO$_2$ >98% reported on day 7 in 11 patients; no response reported in 2 patients. No patients died. 18

<td>Phase 3 randomized, double-blind, placebo-controlled, global clinical trial (NCT04362137; RUXCOVID) failed to confirm efficacy of ruxolitinib in 432 patients ≥12 years of age with COVID-19-associated cytokine storm (sponsored by Novartis/Incyte). Manufacturer announced results (not peer reviewed) indicating that ruxolitinib (5 mg orally twice daily for 14 days, with possible extension to 28 days) plus standard care did not reduce the proportion of patients experiencing severe complications (death, respiratory failure requiring mechanical ventilation, or ICU admission) by day 29, compared with standard care alone (12 vs. 11.8%); in addition, no clinically relevant benefits were observed among secondary or exploratory end points, including mortality rate by day 29 and time to recovery.</td>

<tr>
<td>** Phase 3, randomized, double-blind, placebo-controlled clinical trial (NCT04377620; RUXCOVID-DEVENT; 369 DEVENT) failed to confirm the primary efficacy end point for ruxolitinib in 211 patients ≥12 years of age with COVID-19-associated acute respiratory distress syndrome (ARDS) who required mechanical ventilation (sponsored by Incyte). Manufacturer announced results (not peer reviewed) indicating that ruxolitinib (5 or 15 mg orally twice daily) plus standard care did not reduce all-cause mortality (adjusted for ARDS severity) through day 29 compared with placebo plus standard care (5 mg vs. placebo: 55.2 vs. 74.3%; 15 mg vs. placebo: 51.8 vs. 69.6%). Manufacturer announced that a mortality benefit was observed when data for both dosages were pooled; a mortality benefit also was observed for both the 5- and 15-mg dosages in the subset of patients enrolled in the U.S. (n = 191). Most patients received concurrent or prior therapy with remdesivir (55%) and corticosteroids (90%). The study was terminated at the time of the above planned interim analysis. Initial targeted enrollment was 500 patients.</td>

** Updated 4/30/21

** NIH COVID-19 Treatment Guidelines Panel states that there are insufficient data for the Panel to recommend either for or against use of sarilumab for hospitalized patients with COVID-19 who are within 24 hours of admission to the ICU and who require invasive mechanical ventilation, noninvasive ventilation, or high-flow oxygen (>0.4 FiO₂/30 L/min oxygen flow) 7 (See Tocilizumab in this Evidence Table.)

** No new safety findings observed with use in COVID-19 patients 9

| ** ** | ** ** | ** ** | ** ** | ** ** | ** ** |

Large US-based controlled study (NCT04315298): Dosage of 400 mg IV as a single dose or multiple doses (based on protocol criteria); the lower-dose (200-mg) treatment arm was discontinued following a preliminary analysis of study results 9, 10 (see Trials or Clinical Experience)

In the REMAP-CAP trial, patients received a single 400-mg IV dose 13

Note: IV formulation not commercially available in the U.S., but was studied in the above-mentioned clinical trial. The sub-Q formulation is not FDA-labeled to treat cytokine release syndrome (CRS) in the U.S. 7

** NIH COVID-19 Treatment Guidelines Panel states that there are insufficient data for the Panel to recommend either for or against use of sarilumab for hospitalized patients with COVID-19 who are within 24 hours of admission to the ICU and who require invasive mechanical ventilation, noninvasive ventilation, or high-flow oxygen (>0.4 FiO₂/30 L/min oxygen flow) 7 (See Tocilizumab in this Evidence Table.)

No new safety findings observed with use in COVID-19 patients 9
meet its primary endpoint and key secondary endpoint when sarilumab was compared with placebo in addition to usual hospital care. Although not statistically significant, trends were observed toward a decrease in duration of hospital stay, an acceleration in time to improved clinical outcomes, reduced mortality in the critically ill patient group not seen in the severely ill group, and a shortened time to discharge. 9,11

**Multicenter, ongoing, international open-label trial using a randomized, embedded multifactorial adaptive platform (NCT02735707; REMAP-CAP):** This trial randomized patients to multiple interventions within multiple domains. In the COVID-19 immune modulation therapy domain, adults with suspected or confirmed COVID-19 following admission to an ICU for respiratory or cardiovascular organ support were randomized to receive either tocilizumab (353 patients; 8 mg/kg by IV infusion over 1 hour; dose may be repeated 12-24 hours later) or sarilumab (48 patients; single 400-mg dose by IV infusion over 1 hour) or standard care (402 patients; control group; corticosteroids were included as standard of care) within 24 hours of commencing organ support in an intensive care unit. Over 80% of the patients in the study received corticosteroids. The primary outcome was an ordinal scale combining in-hospital mortality and days free of organ support to day 21. Compared with standard care, treatment with sarilumab or tocilizumab decreased in-hospital mortality (mortality was 22% for sarilumab and 28% for tocilizumab vs 36% for the standard of care). Compared with standard care, sarilumab and tocilizumab also improved in-hospital survival and increased the number of organ support-free days. 7,13

**Italian case series (Benucci et al.)** describes 8 patients hospitalized with COVID-19 pneumonia at one hospital in Florence treated with sarilumab (initial 400-mg IV dose followed by 200-mg IV doses after 48 and 96 hours) in addition to standard therapy (hydroxychloroquine, azithromycin, darunavir, cobicistat, enoxaparin).

<td>Sarilumab</td>
<td>10:00</td>
<td>Antineoplastic agents</td>
<td>Recombinant chimeric monoclonal antibody specific for the interleukin-6 (IL-6) receptor; may potentially combat cytokine release syndrome (CRS) symptoms (e.g., fever, organ failure, death) in severely ill patients</td>
<td>Only limited, unpublished data available describing efficacy in patients with COVID-19. Italy: Non-peer-reviewed findings from an observational cohort study of 30 patients with COVID-19 and pneumonia/acute respiratory distress syndrome (ARDS) who participated in a compassionate use program in one hospital in Italy (SISCO study; NCT04322188) and were followed for at least 30 days showed reduced C-reactive protein (CRP) levels by day 14. The siltuximab-treated patients were compared with 30 propensity score-matched patients receiving best supportive care. The 30-day mortality rate was substantially lower in the siltuximab group compared with the matched-control cohort. Out of the 30 patients treated with siltuximab, 16 (53%) were discharged from the hospital, 4 (13%) remained hospitalized on mechanical ventilation, and 10 patients died.</td>
<td>In the SISCO study in Italy, patients received an initial dose of siltuximab 11 mg/kg by IV infusion over 1 hour; a second dose could be administered at the physician’s discretion. Other clinical studies under way are evaluating a single siltuximab dose of 11 mg/kg by IV infusion. Efficacy and safety of siltuximab in the treatment of COVID-19 not established. NIH COVID-19 Treatment Guidelines Panel recommends against use of siltuximab in the treatment of COVID-19, except in a clinical trial. Pediatric use: Safety and efficacy of siltuximab have not been established in pediatric patients.</td>

| Tocilizumab  | 92:36      | Recombinant humanized monoclonal antibody specific for the interleukin-6 (IL-6) receptor; IL-6 is a proinflammatory cytokine. Tocilizumab may potentially combat cytokine release syndrome (CRS) and pulmonary symptoms in severely ill COVID-19 patients | Results from randomized clinical trials evaluating efficacy of tocilizumab in the treatment of patients with COVID-19 have been conflicting.  
In preliminary data from a non-peer-reviewed, single-arm, observational Chinese trial (Xu et al.) involving 21 patients with severe or critical COVID-19 infection, patients demonstrated rapid fever reduction and a reduced need for supplemental oxygen within several days after receiving tocilizumab (initially given as a single 400-mg dose by IV infusion; this dose was repeated within 12 hours in 3 patients because of continued fever)  
In a retrospective, observational study in China (Luo et al.) involving 15 patients moderately to critically ill with COVID-19, tocilizumab (80-600 mg per dose) was given, and was used in conjunction with methylprednisolone in 8 of the patients. About one-third of the patients received 2 or more doses of tocilizumab. Elevated C-reactive protein (CRP) levels rapidly decreased in most patients following treatment, and a gradual decrease in IL-6 levels was noted in patients who stabilized following tocilizumab administration. Clinical outcomes were equivocal.  
TOCILIZUMAB IS TYPICALLY GIVEN IV TO TREAT CYTOKINE RELEASE SYNDROME (CRS) AND IN PATIENTS WITH COVID-19; HOWEVER, THE DRUG HAS BEEN GIVEN SUBCUtANEOUSLY IN SOME PATIENTS.  
IN THE REMAP-CAP TRIAL, PATIENTS RECEIVED A SINGLE DOSE OF 8 MG/KG BASED ON ACTUAL BODY WEIGHT (UP TO A MAXIMUM OF 800 MG) BY IV INFUSION; THIS DOSE COULD BE REPEATED 12-24 HOURS LATER AT THE DISCRETION OF THE TREATING CLINICIAN.  
BASED ON THE RESULTS FROM THE REMAP-CAP AND RECOVERY TRIALS, THE NIH COVID-19 TREATMENT GUIDELINES PANEL RECOMMENDS A SINGLE 8-MG/KG DOSE (BASED ON ACTUAL BODY WEIGHT) OF TOCILIZUMAB BY IV INFUSION (UP TO A MAXIMUM OF 800 MG) IN ADDITION TO DEXAMETHASONE (6 MG DAILY FOR ≤10 DAYS) IN CERTAIN PATIENTS (SEE COMMENTS COLUMN). AN ALTERNATIVE CORTIcosteroid TO dEXAMETHASONE MAY BE USED IN A THERAPEUTICALLY-EQUIVALENT DOSAGE. THE PANEL STATES THAT DATA ARE INSUFFICIENT TO DETERMINE WHICH PATIENTS, IF ANY, WOULD BENEFIT FROM AN ADDITIONAL DOSE OF TOCILIZUMAB.  | ** NIH COVID-19 Treatment Guidelines Panel has revised recommendations regarding the use of tocilizumab in patients with COVID-19 based on the collective evidence from clinical trials reported to date.**  
The Panel recommends use of tocilizumab (single IV dose of 8 mg/kg of actual body weight, up to 800 mg) in combination with dexamethasone (6 mg daily for ≤10 days) in certain hospitalized patients who are exhibiting rapid respiratory decompensation caused by COVID-19.  
1) Recently hospitalized patients (e.g., within 3 days) admitted to the ICU within the prior 24 hours and who require invasive mechanical ventilation, noninvasive ventilation, or high-flow oxygen (>0.4 FIO2/30 L/min oxygen flow) by nasal cannula.  
2) Recently hospitalized patients (e.g., within 3 days) not admitted to the ICU with rapidly increasing oxygen needs who require noninvasive ventilation or high-flow nasal cannula oxygen and who have significantly increased markers of inflammation (CRP ≥75 mg/L).  |

<td><strong>Zhang et al. from China reported on a patient with COVID-19 and multiple myeloma who appeared to be successfully treated with tocilizumab.</strong>&lt;sup&gt;13&lt;/sup&gt;</td>
<td>For hospitalized patients with hypoxemia who require conventional oxygen therapy, the Panel states that there is currently insufficient evidence to specify which of these patients would benefit from the addition of tocilizumab. Some Panel members would also use tocilizumab in patients exhibiting rapidly increasing oxygen needs while on dexamethasone and who have a CRP ≥75 mg/L, but who do not yet require noninvasive ventilation or high-flow oxygen as described above.&lt;sup&gt;9&lt;/sup&gt;</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td><strong>France: An investigator-initiated, multicenter, open-label, randomized clinical trial (CORIMUNO-TOCI, NCT04331808) evaluated tocilizumab in patients hospitalized at Assistance Publique – Hôpitaux de Paris hospitals in Paris.</strong>&lt;sup&gt;15,16,20&lt;/sup&gt; Sixty-four out of 131 adults with moderate to severe COVID-19 pneumonia not requiring intensive care upon admission were randomized to receive tocilizumab 8 mg/kg (1–2 doses) along with standard of care, and 67 patients were randomized to receive standard of care alone. Tocilizumab did not reduce scores on the World Health Organization 10-point Clinical Progression Scale (WHO-CPS) to ≤5 on day 4 but may have reduced the risk of noninvasive ventilation, mechanical ventilation, or death by day 14. No difference in day 28 mortality was found.&lt;sup&gt;10&lt;/sup&gt;</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The Panel states that use of tocilizumab should be avoided in patients with significant immunosuppression, particularly in those with a history of recent use of biologic immunomodulating drugs; alanine transaminase levels >5 times the upper limit of normal; high risk for GI perforation; uncontrolled, serious bacterial, fungal, or non-SARS-CoV-2 viral infection; or absolute neutrophil count <500 cells/µL; platelet count <50,000 cells/µL, or known hypersensitivity to tocilizumab.<sup>9</sup>

In addition, the Panel states the following:

**Tocilizumab should only be given in combination with dexamethasone (or another corticosteroid at an equivalent dose).**<sup>5</sup>

Some clinicians may assess a patient’s clinical response to dexamethasone first before deciding whether tocilizumab is needed.<sup>9</sup>

Although some patients in the REMAP-CAP and RECOVERY trials received a second dose of tocilizumab at the treating physician’s discretion, there are insufficient data to determine which patients, if any, would benefit from an additional dose of the drug.<sup>9</sup>

Cases of severe and disseminated strongyloidiasis reported with the use of tocilizumab and corticosteroids in patients with COVID-19. Prophylactic

| US/Global randomized, placebo-controlled trial: Manufacturer (Roche) conducted a randomized, double-blind, placebo-controlled phase 3 trial (COVACTA; NCT04320615) in collaboration with the US Health and Human Services’ Biomedical Advanced Research Development Authority (BARDA). The study evaluated safety and efficacy of tocilizumab in combination with standard of care compared with placebo in adults hospitalized with severe COVID-19 pneumonia. The trial failed to meet its primary endpoint of improved clinical status at week 4 (determined using a 7-point scale to assess clinical status based on need for intensive care and/or ventilator use and requirement for supplemental oxygen) and several key secondary endpoints, including the key secondary endpoint of reduced patient mortality.  

**Boston Area COVID-19 Consortium (BACC) Bay Tocilizumab Trial:** In this investigator-driven, randomized, placebo-controlled trial (NCT04356937), 243 adults with confirmed severe COVID-19, hyperinflammatory states, and at least 2 of the following signs: fever (body temperature >38°C), pulmonary infiltrates, or need for supplemental oxygen in order to maintain SpO<sub>2</sub> >92% were randomly assigned in a 2:1 ratio to receive standard care plus a single IV dose of either tocilizumab (8 mg/kg) or placebo. The primary outcome was intubation or death, assessed in a time-to-event analysis. Secondary efficacy outcomes were clinical worsening and discontinuation of supplemental O<sub>2</sub> among patients who had been receiving it at baseline, both assessed in time-to-event analyses. 58% of the enrolled patients were men, median age was 59.8 years (range: 21.7 to 85.4 years), and 45% of patients were Hispanic or Latino. The hazard ratio for intubation or death in the tocilizumab group compared with the placebo group was 0.83 (P = 0.64), and the hazard ratio for disease worsening was 1.11 (P = 0.73). At 14 days, 18% of the pts in the tocilizumab group and 14.9% of those in the placebo group had worsening of disease. Median time to discontinuation of supplemental O<sub>2</sub> was 5 days in the tocilizumab group and 4.9 days in the placebo group. | ivermectin should be considered for individuals who are from areas where strongyloidiasis is endemic.  

**Pediatric use:** There are insufficient data to recommend either for or against tocilizumab for the treatment of hospitalized children with COVID-19 or multi-system inflammatory syndrome of children (MIS-C). Tocilizumab has been used in children to treat cytokine release syndrome associated with CAR-T cell therapy and systemic and polyarticular juvenile idiopathic arthritis.  

The role of routine cytokine measurements (e.g., IL-6, CRP) in determining the severity of and treating COVID-19 requires further study. |
At 14 days, 24.6% of patients in the tocilizumab group and 21.2% of those in the placebo group were still receiving supplemental O₂. Patients who received tocilizumab had fewer serious infections than patients who received placebo. Tocilizumab was not found to be effective for preventing intubation or death in moderately ill hospitalized patients with COVID-19 in this study. Some benefit or harm cannot be ruled out, however, because the confidence intervals for efficacy comparisons were wide.¹⁹

Multicenter, ongoing, international open-label trial using a randomized, embedded multifactorial adaptive platform (NCT02735707; REMAP-CAP): This trial randomized patients to multiple interventions within multiple domains. In the COVID-19 immune modulation therapy domain, adults with suspected or confirmed COVID-19 following admission to an ICU for respiratory or cardiovascular organ support were randomized to receive either tocilizumab (353 patients; 8 mg/kg by IV infusion over 1 hour; dose may be repeated 12-24 hours later) or sarilumab (48 patients; single 400-mg dose by IV infusion over 1 hour) or standard care (402 patients; control group; corticosteroids were included as standard of care) within 24 hours of commencing organ support in an intensive care unit. Over 80% of the patients in the study received corticosteroids. The primary outcome was an ordinal scale combining in-hospital mortality and days free of organ support to day 21. Compared with standard care, treatment with sarilumab or tocilizumab decreased in-hospital mortality (mortality was 22% for sarilumab and 28% for tocilizumab vs 36% for the standard of care). Compared with standard of care, sarilumab and tocilizumab also improved in-hospital survival and increased the number of organ support-free days.⁹, ²¹

Randomized, controlled, open-label, platform trial (NCT04381936; RECOVERY): The RECOVERY trial is assessing several possible treatments in patients hospitalized with COVID-19 in hospitals throughout the UK. Up to 21 days following the initial (main) randomization and regardless
of the initial treatment allocation, participants in the RECOVERY trial with clinical evidence of progressive COVID-19 characterized by hypoxia (O₂ saturation <92% on air or requiring oxygen therapy) and evidence of systemic inflammation (CRP concentrations ≥75 mg/L) could be considered for randomization to tocilizumab plus usual care or usual care alone. Preliminary results (not peer reviewed) for a total of 2094 adults randomized to receive usual standard of care alone and 2022 adults randomized to receive tocilizumab by IV infusion (400-800 mg, based on weight; a second dose could be given within 12-24 hours) in addition to usual standard of care are available. At the time of randomization, 82% of these patients were receiving corticosteroids. The primary outcome measure was 28-day mortality; 596 patients (29%) in the tocilizumab group died within 28 days compared with 694 patients (33%) in the standard of care group. Patients concurrently receiving corticosteroids and tocilizumab showed a clear mortality benefit. Patients who received tocilizumab also were more likely to be discharged from the hospital alive within 28 days than those receiving standard of care alone (54 versus 47%, respectively). These benefits were seen in all patient subgroups, including those requiring oxygen via a simple face mask through to those requiring mechanical ventilation in an ICU. Among patients not receiving invasive mechanical ventilation at baseline, tocilizumab was associated with a substantially lower risk of progressing to invasive mechanical ventilation or death compared with standard of care alone (38 versus 33%, respectively). There was no evidence that tocilizumab had any effect on the chance of successful cessation of invasive mechanical ventilation.²²

Various clinical trials evaluating tocilizumab for the treatment of COVID-19 are registered at clinicaltrials.gov.⁷

| Vitamin D      |            | Vitamin D receptor is expressed on immune cells (e.g., B cells, T cells, antigen-presenting cells); these cells can synthesize and respond to active vitamin D. | Only limited prospective clinical trial evidence regarding efficacy of vitamin D supplementation for treatment or prevention of COVID-19.  
**Prevention of respiratory infections:**  Efficacy of vitamin D supplementation for prevention of influenza or other respiratory infections is unclear.  
Meta-analysis of 25 randomized, double-blind, placebo-controlled trials involving a total of 11,321 participants, either healthy or with comorbidities, indicated a protective effect for oral vitamin D supplementation against acute respiratory infection.  
A second systematic review and meta-analysis of 15 randomized controlled trials involving approximately 7000 healthy individuals found that vitamin D supplementation did not reduce the risk of respiratory infections compared with placebo or no treatment.  
**Outcomes in critically ill patients:**  Results of 2 randomized, double-blind, placebo-controlled clinical trials (VIOLET, VITdAL-ICU) in critically ill patients with vitamin D deficiency (but not with COVID-19) indicated that high-dose vitamin D did not reduce hospital stay or mortality rate compared with placebo. Patients in both studies received a single enteral dose of 540,000 international units (IU; units) of vitamin D2; patients in VITdAL-ICU also received oral maintenance doses (90,000 units monthly for 5 months).  
**Outcomes in patients with COVID-19:**  Retrospective study (NCT04560608) in frail geriatric patients (mean age: 88 years; range: 78-100 years) hospitalized with COVID-19 suggested lower frequency of severe COVID-19 disease and lower 14-day mortality in those who received regular oral vitamin D supplementation (50,000 units monthly or 80,000 or 100,000 units every 2-3 months) over the prior year (n = 29) compared with those who received no supplementation, either over the prior year or following COVID-19 diagnosis (n = 32).  
Various dosages of vitamin D are being evaluated for prevention or treatment of COVID-19.  
High concentrations of vitamin D may cause hypercalcemia and nephrocalcinosis; currently no convincing scientific evidence that very high intake of vitamin D will be beneficial in preventing or treating COVID-19.  
National Academy of Sciences (NAS) guidelines for **adequate dietary intake of vitamin D for bone health in US population:**  Estimated Average Requirement (EAR) in children and adults 1-70 years of age is 400 units (10 mcg) daily; Recommended Dietary Allowance (RDA) in these age groups is 600 units (15 mcg) daily. In adults >70 years of age, EAR is 400 units (10 mcg) daily and RDA is 800 units (20 mcg). These reference values assume minimal sun exposure.  
NAS states that data indicate that a serum 25-hydroxyvitamin D concentration of 50 nmol/L is sufficient to meet the needs of 97.5% of the population and concentrations <30 nmol/L are associated with clinical deficiency.  
Efficacy of vitamin D supplementation in the prevention or treatment of COVID-19 has not been established. Some experts recommend maintaining recommended levels of vitamin D intake during the COVID-19 pandemic to maintain bone and muscle health and avoid deficiency.  
NIH COVID-19 Treatment Guidelines Panel states that there are insufficient data to recommend either for or against use of vitamin D for prevention or treatment of COVID-19.  
Joint guidance from the American Society for Bone and Mineral Research (ASBMR), American Association of Clinical Endocrinologists (AACE), Endocrine Society, European Calcified Tissue Society (ECTS), National Osteoporosis Foundation (NOF), and International Osteoporosis Foundation (IOF) emphasizes importance of obtaining the recommended daily dosage of vitamin D; for those unable to obtain recommended durations of direct sun exposure during the pandemic, recommended intake of vitamin D can be obtained through supplemental vitamin D. The joint guidance states that current data do not provide any evidence that vitamin D supplementation will help prevent or treat COVID-19.  
** Recommendations from the UK National Institute for Health and Care Excellence (NICE) state that there is insufficient evidence to recommend use of vitamin D supplements solely to prevent or treat COVID-19, except as part of a clinical trial. However, all individuals should continue to follow current recommendations on daily vitamin D supplementation to maintain bone and muscle health during the pandemic.  |
Vitamin D deficiency is associated with increased autoimmunity and increased susceptibility to infection. In observational studies, low vitamin D concentrations have been associated with increased risk of community-acquired pneumonia in older adults and upper respiratory viral infections in children.  
Vitamin D deficiency is common in the U.S., particularly in Hispanic and Black populations (groups overrepresented among U.S. COVID-19 cases).  
Vitamin D deficiency is overrepresented among particularly in Hispanic and Black populations (groups overrepresented among U.S. COVID-19 cases).  |

*Dosage values assume minimal sun exposure. EAR = Estimated Average Requirement, RDA = Recommended Dietary Allowance.  
** Recommendations from the UK National Institute for Health and Care Excellence (NICE) state that there is insufficient evidence to recommend use of vitamin D supplements solely to prevent or treat COVID-19, except as part of a clinical trial. However, all individuals should continue to follow current recommendations on daily vitamin D supplementation to maintain bone and muscle health during the pandemic.

**Zinc**<br>Updated 4/30/21 | Trace mineral involved in immune function, including antibody and white blood cell production; an important cofactor for many enzymes; <sup>1,3</sup> may improve wound healing<sup>8</sup> | Zinc deficiency increases proinflammatory cytokine | No evidence from controlled trials that zinc is effective in the prevention or treatment of COVID-19<sup>5,6</sup> | Zinc Recommended Dietary Allowance (RDA): Adult males: 11 mg/day; adult females: 8 mg/day<sup>5,8</sup> | Despite some anecdotal claims in the media that zinc is effective in treating COVID-19,<sup>6</sup> it remains unclear whether zinc supplementation is beneficial in the prophylaxis and/or treatment of COVID-19; further study is needed<sup>1,3,6</sup> NIH COVID-19 Treatment Guidelines Panel states that there are insufficient clinical data to recommend either for...
concentrations (interleukin-1 [IL-1], IL-6, TNF alpha) and decreases antibody production; zinc supplementation increases the ability of polymorphonuclear cells to fight infection 6.

Possible antiviral activity; zinc appears to inhibit virus RNA polymerase activity and viral replication in an in vitro and cell culture model of severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1). 5, 7 High-dose zinc supplementation reduced the duration but not severity of common cold symptoms compared with placebo in a meta-analysis 1, 3, 7.

Zinc enhances cytotoxicity and induces apoptosis when used in vitro with a zinc ionophore (e.g., chloroquine): chloroquine can enhance intracellular zinc uptake in vitro 9.

Elderly patients and patients with certain concurrent medical conditions are at higher risk of zinc deficiency 2, 3, 8.

and those who received hydroxychloroquine and azithromycin alone (521 patients). Zinc was given as a zinc sulfate 220-mg capsule (50 mg of elemental zinc) twice daily for 5 days. The addition of zinc did not affect the length of hospitalization, duration of ventilation, or duration of ICU stay, but patients in the treatment group that included zinc were discharged home more frequently and the need for ventilation, ICU admission, and mortality or transfer to hospice for patients not admitted to the ICU were all reduced in univariate analyses. After adjusting for the timing of when zinc was added to the protocol, findings remained significant for increased frequency of being discharged home and reduction in mortality or transfer to hospice in the zinc-treated patients. Because of the study design and its limitations, the authors state that this study should not be used to guide clinical practice, but that the observations do support initiation of randomized controlled trials investigating zinc in patients with COVID-19. 11

Multicenter, retrospective, cohort study in New York City hospitals (Yao et al; non-peer-reviewed): This study reviewed the records of 3473 hospitalized adults with laboratory-confirmed COVID-19 who were admitted to 4 New York City hospitals between March 10 and May 20, 2020. The primary aim of the study was to compare rates of in-hospital mortality among patients who received zinc plus hydroxychloroquine and those not receiving this combination. Out of 3473 patients, 1006 (29%) received zinc and hydroxychloroquine in combination and 2467 (71%) received hydroxychloroquine without zinc. Zinc plus hydroxychloroquine was associated with a 24% reduced risk of in-hospital mortality compared with patients who did not receive the combination (12 versus 17% respectively; p<0.001). In addition, hospital discharge rates were substantially higher in patients receiving the combination versus those who did not (72 versus 67%; p=0.003). Neither zinc nor hydroxychloroquine alone were associated with decreased mortality rates. 34 There are several limitations to this study. It was a

Appropriate dosage regimens not established in either the prophylaxis or treatment of COVID-19; various supplementation regimens being evaluated in clinical trials, with a maximum dosage of zinc sulfate of 220 mg (50 mg of elemental zinc) twice daily 2, 5, 6, 9, 10, 11, 12, 13.

NCT04342728 (COVID A to Z): Oral zinc gluconate 50 mg (of elemental zinc) once daily, given at bedtime for 10 days after diagnosis, did not reduce duration of symptoms in outpatients 11.

Oral zinc supplementation likely safe in dosages up to 40 mg of elemental zinc daily in adults; safety of dosages exceeding those used in the management of the common cold not known 3, 6, 8.

Zinc concentrations are difficult to measure accurately since it is distributed as a component of various proteins and nucleic acids 9.

Adverse effects may include nausea (possibly dose dependent), vomiting, and changes in taste 1, 6, 7, 8.

Long-term zinc supplementation may cause copper deficiency with adverse hematologic (e.g., anemia, leukopenia) and neurologic effects (e.g., myelopathy, paresthesia, ataxia, spasticity); zinc supplementation for as little as 10 months has been associated with copper deficiency 9.

Intranasal administration should be avoided because of reports of prolonged or permanent loss of the sense of smell; intranasal zinc formulations are no longer commercially available in the US 6, 8.

Potential for interactions with iron and copper, certain antibiotics (e.g., quinolones, tetracyclines), and other medications 8.

<td>Retrospective observational study at a single institution (Hoboken University Medical Center): This study collected data on 242 patients with laboratory-confirmed COVID-19 who were admitted to the hospital. 196 of the patients (81%) received a total daily dosage of zinc sulfate 440 mg (100 mg of elemental zinc); 191 of these patients (97%) also received hydroxychloroquine. The primary outcome was days from admission to in-hospital mortality. The primary analysis explored the causal relationship between zinc administration and patient survival. There were no significant differences in baseline characteristics between the 2 groups of patients. 73 patients (37.2%) died in the zinc group compared with 21 patients (45.7%) in the control group. In the primary analysis, which used inverse probability weighting (IPW), the effect estimate of zinc therapy was an additional 0.84 days of survival. This finding was considered imprecise. On multivariate Cox regression analysis with IPW, zinc therapy was not significantly associated with a change in the risk of in-hospital mortality and the use of interleukin-6 inhibitors was associated with reduced mortality. Older patients, male patients, and those with severe or critical disease were significantly associated with increased mortality. $^{14}$</td>

<td>ACE Inhibitors, Angiotensin II Receptor Blockers (ARBs)</td>
<td>24:32 Renin-Angiotensin-Aldosterone System Inhibitor</td>
<td><strong>Hypothetical harm:</strong> Human pathogenic coronaviruses bind to their target cells through angiotensin-converting enzyme 2 (ACE2). Expression of ACE2 may be increased in patients treated with ACE inhibitors or ARBs. Increased expression of ACE2 may potentially facilitate COVID-19 infections.</td>
<td>Only limited data available to date evaluating the effect of these drugs on COVID-19 infection.</td>
<td></td>
<td>American Heart Association (AHA), American College of Cardiology (ACC), Heart Failure Society of America (HFSA), and European Society of Cardiology (ESC) recommend continuation of treatment with renin-angiotensin-aldosterone system (RAAS) antagonists in those patients who are currently prescribed such agents. These experts state there is a lack of experimental or clinical data demonstrating beneficial or adverse outcomes among COVID-19 patients receiving ACE inhibitors or ARBs. Further study is needed. <strong>NIH COVID-19 Treatment Guidelines</strong> Panel states patients who are receiving an ACE inhibitor or ARB for cardiovascular disease (or other non-COVID-19 indications) should not discontinue these drugs during acute management of COVID-19 unless discontinuation is otherwise warranted by their clinical condition. The panel <strong>recommends against</strong> use of ACE inhibitors or ARBs for the treatment of COVID-19 except in the context of a clinical trial. These experts state that it is unclear whether use of ACE inhibitors or ARBs has a positive or negative impact on the treatment and clinical outcomes of COVID-19. Meta-analyses and ongoing reviews have not found an association between the use of such medications and the likelihood of a positive result from SARS-CoV-2 testing or on the severity or outcomes of COVID-19 infection. Patients with cardiovascular disease are at an increased risk of severe COVID-19. Abrupt withdrawal of RAAS inhibitors in high-risk patients (e.g., heart failure patients, patients with prior myocardial infarction) may lead to clinical instability and adverse health outcomes.</td>
</tr>
<tr>
<td><strong>Updated 4/30/21</strong></td>
<td></td>
<td>** Hypothetical benefit:** ACE inhibitors or ARBs may have a protective effect against lung damage or may have paradoxical effect in terms of virus binding. Large, observational study analyzed a cohort of pts tested for COVID-19 to evaluate the relationship between previous treatment with 5 common classes of antihypertensive agents (including ACE inhibitors, ARBs) and the likelihood of a positive or negative test result for COVID-19 as well as the likelihood of severe COVID-19 illness among pts who tested positive: Study included data obtained from a large health network in New York City for 12,594 pts who were tested for COVID-19 from Mar 1 to Apr 15, 2020. Among these pts, 4357 (34.6%) had a history of hypertension. Of these patients, 2573 (59.1%) tested positive for COVID-19. Among the 2573 pts with hypertension and positive results for COVID-19, 634 pts (24.6%) had severe disease (indicated by hospitalization, mechanical ventilation, or death). Results of COVID-19 testing were stratified in propensity-score-matched patients with hypertension according to previous treatment with selected antihypertensive agents. Propensity-score matching was based on age, sex, race, BMI, medical history, various comorbidities, and other classes of medications. The authors stated that no substantial increase was observed in the likelihood of a positive test for COVID-19 or in the risk of severe COVID-19 among patients who tested positive in association with any single antihypertensive class (including ACE inhibitors, ARBs).</td>

| matched to 30,759 controls based on sex, age, and place of residence. Information about use of selected drugs and clinical profiles was obtained from regional healthcare databases. Use of ACE inhibitors or ARBs was more frequent in patients with COVID-19 than among controls because of their higher prevalence of cardiovascular disease. Percentage of patients receiving ACE inhibitors was 23.9% for case pts and 21.4% for controls. Percentage of patients receiving ARBs was 22.2% and 19.2% for case and control pts, respectively. The authors concluded that there was no evidence that treatment with ACE inhibitors or ARBs significantly affected the risk of COVID-19 or altered the course of infection or resulted in more severe disease. |

**Large, multinational, retrospective study analyzed outcome data for hospitalized pts with confirmed COVID-19 to evaluate the relationship between cardiovascular disease and preexisting treatment with ACE inhibitors or ARBs with COVID-19** (Mehra et al; now retracted): Original publication included multinational data for 8910 pts hospitalized with COVID-19 between Dec 20, 2019 and Mar 15, 2020 that were obtained from a global healthcare data collaborative. The authors concluded that those data confirmed previous observations suggesting that underlying cardiovascular disease is independently associated with an increased risk of death in hospitalized pts with COVID-19. They also stated that they were not able to confirm previous concerns regarding a potential harmful association of ACE inhibitors or ARBs with in-hospital mortality. **Note: This published study has now been retracted by the publisher at the request of the original authors. Concerns were raised with respect to the veracity of the data and analyses that were the basis of the authors’ conclusions.**

**Multicenter, prospective study in a cohort of hospitalized pts with confirmed COVID-19 infection to evaluate the association of antihypertensive therapy with ACE inhibitors or ARBs and the risk of severe COVID-19 or worsening of clinical outcomes**

<tr>
<td>(NCT04357535; Hakeam et al): Data are available for 338 patients from 4 hospitals in Saudi Arabia. On the day of hospital admission, 245 of these patients (72.5%) were receiving ACE inhibitors or ARBs; 197 of these patients continued such antihypertensive therapy during hospitalization. On the day of hospital admission, 93 patients (27.5%) were receiving antihypertensive therapy (e.g., calcium-channel blockers, β-blockers, thiazide diuretics) that did not include either ACE inhibitors or ARBs. The primary study end point was the rate of developing severe COVID-19 on the day of hospitalization. The key secondary end point was a composite of mechanical ventilation and in-hospital mortality. In the study cohort, 98 patients (29%) met the WHO criteria for severe COVID-19 on the day of hospitalization. However, use of ACE inhibitors or ARBs was not associated with development of severe COVID-19 (odds ratio: 1.17). Use of ACE inhibitors or ARBs prior to hospitalization also was not associated with ICU admission, mechanical ventilation, or in-hospital mortality. In addition, continuing such antihypertensive therapy during non-ICU hospitalization was associated with decreased mortality (odds ratio: 0.22). The authors concluded that patients with hypertension or cardiovascular disease receiving therapy with ACE inhibitors or ARBs prior to hospitalization for COVID-19 do not appear to be at increased risk for severe infection upon hospital admission. In addition, ICU admission, mechanical ventilation, and mortality are not associated with use of ACE inhibitors or ARBs prior to hospitalization. Because of a lower risk of mortality, the authors advise that ACE inhibitor or ARB therapy be continued in pts with COVID-19 during hospitalization. However, because of study limitations, randomized controlled trials are needed for further assessment of the effects of ACE inhibitors or ARBs on COVID-19. 15 Multicenter, open-label, randomized study in hospitalized pts with mild to moderate COVID-19 to evaluate the effect of discontinuation versus continuation of ACE inhibitors or ARBs on clinical outcomes (NCT04364893; Lopes et al): Data are...</td>

<td></td>
<td>available for 659 adults from 29 hospitals in Brazil who were receiving ACE inhibitors or ARBs prior to hospitalization. In the primary analysis, 334 of these patients were randomized to discontinue ACE inhibitors or ARBs and 325 patients were assigned to continue use of such medication for 30 days. The primary study end point was the number of days alive and out of the hospital from randomization through 30 days. Key secondary end points included death during the 30-day follow-up period, cardiovascular death, and COVID-19 progression. No significant difference was observed in the mean number of days alive and out of the hospital for patients in the discontinuation group (21.9 days) compared with patients in the continuation group (22.9 days). There were also no significant differences between the discontinuation and the continuation groups in the incidence of death (2.7 versus 2.8%, respectively), cardiovascular death (0.6 versus 0.3%, respectively), or COVID-19 progression (38.3 versus 32.3%, respectively). The authors concluded that these findings do not support the routine discontinuation of ACE inhibitors or ARBs among hospitalized patients with mild to moderate COVID-19 when there is an indication for such use. Limitations of this trial include the open-label study design and the lack of generalizability of results to COVID-19 patients in other settings. The study also was not designed to evaluate the effect of ACE inhibitors or ARBs on susceptibility to COVID-19.(^{18}) Clinical trials completed; results not yet published (losartan): Initiation of losartan in adults with COVID-19 requiring hospitalization; primary outcome measure: sequential organ failure assessment (SOFA) respiratory score (NCT04312009). Initiation of the drug in adults with COVID-19 not requiring hospitalization; primary outcome measure: treatment failure resulting in hospital admission (NCT04311177).(^7) Other clinical trials evaluating the effect of continuing or discontinuing treatment with ACE inhibitors or ARBs on clinical outcomes in patients with COVID-19 are registered at clinicaltrials.gov.(^7)</td>

<td>Anticoagu-</td>
<td>20:12.04</td>
<td>Patients with COVID-19, particularly those with severe disease, may develop a hypercoagulable state, which can contribute to poor outcomes (e.g., progressive respiratory failure, acute respiratory distress syndrome [ARDS], death). Most common pattern of coagulopathy is characterized by elevated D-dimer levels, high fibrinogen levels, minimal prolongation of aPTT and/or PT, and mild thrombocytopenia; microvascular and macrovascular thrombosis also have been reported. In addition, high rates of VTE have been observed in critically ill patients with COVID-19. Pathogenesis of COVID-19-related coagulopathy not completely known, but may be associated with endothelial cell activation and other factors contributing to an uncontrolled immunothrombotic response to the virus. Lupus anticoagulants have been detected in some patients with COVID-19 who present with prolonged aPTT; however, clinical significance of these antibodies is not known. Such thrombotic findings are the basis for anticoagulant therapy in COVID-19 patients; some anticoagulant agents also may have antiviral and anti-inflammatory properties. Limited data from a retrospective study in China showed reduced mortality in COVID-19 patients with severe sepsis-induced coagulopathy or markedly elevated D-dimer levels (&gt;6 x ULN) who received prophylactic anticoagulation (low molecular weight heparin [LMWH] or unfractionated heparin [UFH]). In a large (n=4297) observational cohort study using data from the US VA system, early initiation of prophylactic anticoagulation (within 24 hours of admission for COVID-19) was associated with a 27% decreased risk of 30-day mortality compared with no anticoagulation; post-hoc analysis indicated that evidence of benefit appeared to be most pronounced in patients who were not admitted to the ICU within the first 24 hours of admission. Results of this study provide some evidence to support guidelines recommending the use of prophylactic anticoagulation as initial treatment for COVID-19 patients on hospital admission (see Comments column). Several retrospective studies suggest that high-intensity prophylactic anticoagulation or therapeutic anticoagulation may be associated with lower mortality compared with standard VTE prophylaxis in severe COVID-19 patients. In one of these studies, systemic anticoagulation in a large cohort (n=786) of hospitalized patients with COVID-19 was associated with reduced risk of mortality; in the subgroup of patients who required mechanical ventilation, mortality rate was reduced with the use of therapeutic anticoagulation compared with no anticoagulation use (29 versus 63%; median survival of 21 versus 9 days). In a subsequent retrospective study involving a larger cohort of patients (n=4389) from the same health system, use of prophylactic or therapeutic anticoagulation was associated with lower in-hospital mortality compared with no anticoagulant therapy (adjusted hazard reductions of 50 and 47%, respectively). Overall bleeding rates were low, but higher in the therapeutic anticoagulation group (3%) compared with...</td>

<td></td>
<td></td>
<td></td>
<td>The available evidence to inform the clinical management of COVID-19-associated coagulopathy is continuously evolving. Several organizations (e.g., NIH, WHO, CDC, American Society of Hematology (ASH), International Society for Thrombosis and Haemostasis, Anticoagulation Forum, Surviving Sepsis Campaign, Mayo Clinic) have published interim guidance for anticoagulation management in patients with COVID-19. These experts agree that hospitalized patients with COVID-19 should receive prophylactic-dose anticoagulation to reduce the risk of thromboembolism unless there are contraindications. However, many questions regarding the best prophylactic strategy in COVID-19 patients remain unanswered (e.g., type and intensity of anticoagulation, duration of anticoagulation, use of biomarkers for VTE risk stratification). VTE risk should be assessed in all hospitalized patients with COVID-19. While initial reports suggested that bleeding is infrequent in COVID-19 patients, more information regarding the risk of bleeding is emerging. Standard risk factors for bleeding should be considered and patients should be individually assessed to balance risk of thrombosis with risk of bleeding. The NIH COVID-19 Treatment Guidelines Panel recommends prophylactic-dose anticoagulation for VTE prophylaxis in all hospitalized adults with COVID-19 unless contraindicated. In pregnant patients hospitalized with severe COVID-19, prophylactic-dose anticoagulation is recommended if there are no contraindications to its use; if antithrombotic therapy is prescribed prior to the diagnosis of COVID-19 in a pregnant patient, such therapy should be continued. For hospitalized children with COVID-19, indications for VTE prophylaxis should...</td>

- the prophylactic or no anticoagulation groups. Among 26 autopsies performed in this cohort of patients, 42% had evidence of thromboembolic disease not otherwise suspected premortem; the majority of these patients were not treated with therapeutic anticoagulation. **40**
- An escalated-dose thromboprophylaxis strategy was evaluated in a retrospective single-center study. COVID-19 patients without severe disease were initiated on standard-dose VTE prophylaxis, while those with severe disease (defined as requiring ICU-level care or D-dimer level greater than 2.5 mg/L FEU and without indications for therapeutic anticoagulation) were considered for escalated-dose thromboprophylaxis (enoxaparin 0.5 mg/kg twice daily or heparin IV infusion titrated to anti-factor Xa levels 0.3-0.5 U/mL in patients with renal failure). The observed rates of VTE (7.3%) and overall thromboembolic events (12%) were lower in this study compared with earlier reported rates, which the authors suggest may be related to early implementation of an escalating thromboprophylactic strategy. **52**
- Another retrospective study evaluated the impact of a tailored anticoagulant approach (risk stratification based on D-dimer and other clinical and laboratory parameters) in COVID-19 patients admitted to the ICU. Standard anticoagulant prophylaxis was used in 83 patients (44%); high-intensity prophylaxis was used in 75 patients (40%); therapeutic anticoagulation was used in 24 patients (12.8%) who had confirmed or clinical suspicion of VTE. The overall rate of thrombotic events in this study was 12.2%, which the authors state is lower than previously reported with severe COVID-19 in the ICU. Major bleeding occurred in 2.7% of patients who received the high-intensity prophylactic regimen and in 21% of patients who received therapeutic anticoagulation. **57**
- In a small (n=20), open-label, phase 2 study, administration of therapeutic-dose enoxaparin in mechanically ventilated COVID-19 patients was associated with improved oxygenation (PaO\textsubscript{2}/FiO\textsubscript{2} ratio),

<td>immediately life-threatening condition who would typically be admitted to the ICU, such as patients requiring hemodynamic support, ventilatory support, or renal replacement therapy) who do not have suspected or confirmed VTE; however, a conditional recommendation is given based on very low certainty of evidence. (See information on the multiplatform, adaptive-design trial that includes REMAP-CAP, ATTACC, and ACTIV-4A in the Clinical Trials and Experience column). ASH discourages the empiric use of full-dose heparin or LMWH outside a clinical trial in critically ill COVID-19 patients who do not have any other indication for therapeutic anticoagulation. In hospitalized patients with COVID-19-related acute illness not requiring intensive care (e.g., those with dyspnea or mild to moderate hypoxia) who do not have suspected or confirmed VTE, ASH suggests the use of prophylactic-intensity over intermediate- or therapeutic-intensity anticoagulation; a conditional recommendation is given based on very low certainty of evidence. Although preliminary findings in the moderately ill patient cohort (those requiring hospitalization but not ICU-level care) suggest that full-dose anticoagulation is superior to usual prophylactic-dose anticoagulation in this population, ASH states that, until peer-reviewed data are available, clinicians should use clinical judgment when managing individual patients and carefully consider the benefits and harms of higher-intensity anticoagulation. In COVID-19 patients who experience recurrent clotting of access devices (e.g., central venous catheters, arterial lines), ASH states that, although of unproven benefit, it may be reasonable to increase the intensity of anticoagulation or switch to a different anticoagulant in these situations. $^{66}$</td>

As of December 21, 2020, enrollment of patients requiring ICU-level care (defined as requiring high-flow nasal oxygen, invasive or noninvasive mechanical ventilation, vasopressor therapy, or ECMO support) was paused due to results of an interim pooled analysis demonstrating futility of full-dose anticoagulation in reducing the need for organ support and mortality compared with usual care prophylactic-dose anticoagulation.\(^5,28,58\) Enrollment is continuing for hospitalized patients not requiring ICU support (i.e., moderately ill patients) in these trials to determine whether there is any benefit from full-dose anticoagulation.\(^58\)

On January 22, 2021, NIH reported interim results of the above multiprotocol trials in the moderately ill cohort. Based on data collected from more than 1000 moderately ill hospitalized patients with COVID-19 (identified as those not in the ICU and not receiving organ support such as mechanical ventilation at trial enrollment), preliminary findings showed that full-dose anticoagulation was superior to prophylactic doses in reducing mortality or the need for organ support.\(^15,63\) Peer-review of the finalized multiprotocol trial data is pending.\(^15\)

Multiple clinical trials are ongoing to evaluate anticoagulant strategies in patients with COVID-19; some are registered at clinicaltrials.gov. As of December 16, 2020, there were 75 randomized controlled trials of antithrombotic therapy in patients with COVID-19; a variety of antithrombotic agents are being investigated.\(^12,43,47,67\)

Emergency use authorization (EUA) high-titer COVID-19 convalescent plasma dosage and administration for hospitalized patients and those with impaired humoral immunity: Consider initiating therapy with one high-titer unit (approximately 200 mL) of COVID-19 convalescent plasma given IV through a peripheral or central venous catheter according to standard institutional transfusion guidelines. Additional high-titer COVID-19 convalescent plasma units may be administered based on the prescribing physician’s medical**

</table>
| Convalescent plasma therapy has been used in the treatment of other viral diseases with various degrees of success. 16, 20, 22, 24, 35 | **Randomized, controlled, open-label, adaptive, platform trial assessing several possible treatments in patients hospitalized with COVID-19 in the UK (NCT04381936; RECOVERY):** Preliminary (non-peer-reviewed) data for 5763 patients randomized to receive standard care and 5795 patients randomized to receive standard care plus convalescent plasma demonstrated no significant differences in 28-day mortality between the two groups (risk ratio: 1.00). Convalescent plasma for this study was prepared using only plasma donations with sample to cut-off (S/CO) ratio of ≥6.0 as detected by the EUROIMMUN IgG ELISA test. 34  
Study with retrospectively matched control in US (Liu et al): Preliminary (non-peer-reviewed) data from a study of 39 hospitalized adults with severe to life-threatening COVID-19 who received ABO-compatible COVID-19 convalescent plasma (2 units [total volume approximately 500 mL] infused IV over 1-2 hours), obtained from donors with a SARS-CoV-2 anti-spike antibody titer of 1:320 or greater, suggest that stable or improved supplemental oxygen requirements by post-transfusion day 14 were more likely in these convalescent plasma recipients than in the matched control group not treated with convalescent plasma (odds ratio: 0.86); this effect appeared to be confounded by use of therapeutic anticoagulants, but not by other types of drugs (i.e., azithromycin, broad-spectrum antibiotics, hydroxychloroquine, corticosteroids, antivirals, interleukin-1 [IL-1] and IL-6 inhibitors) or duration of symptoms before admission. Overall, survival was improved in patients in the convalescent plasma group compared to the control group; after adjusting for covariates, data suggest a significant improvement in survival in non-intubated patients (hazard ratio: 0.19) receiving convalescent plasma, but not in the small cohort of intubated patients (hazard ratio: 1.24). Subgroup analyses suggested a survival benefit of convalescent plasma among nonintubated patients, in those who received treatment earlier in the course of disease, and those who received therapeutic anticoagulation. | judgment and the patient’s clinical response. 37, 38 | Smaller volumes or prolonged transfusion times may be necessary in patients with impaired cardiac function and heart failure. 38 | Emergency use authorization (EUA) for high-titer COVID-19 convalescent plasma: FDA issued an EUA on August 23, 2020 that permitted use of convalescent plasma for the treatment of hospitalized patients with COVID-19. This EUA was reissued in its entirety on February 4, 2021 to authorize the use of high-titer COVID-19 convalescent plasma for the treatment of hospitalized patients with COVID-19, early in the course of disease, and in those hospitalized with COVID-19 who have impaired humoral immunity. Use of low-titer COVID-19 convalescent plasma is no longer authorized under the EUA. This EUA is based on historical evidence using convalescent plasma in prior outbreaks of respiratory viruses, certain preclinical evidence, results from small clinical trials of convalescent plasma conducted during the current outbreak, data obtained from the ongoing National Expanded Access Treatment Protocol (EAP) for COVID-19 convalescent plasma sponsored by the Mayo Clinic, and additional studies (including randomized controlled trials). 37 The EUA requires healthcare providers to provide convalescent plasma recipients with the Fact Sheet for Patients and Parents/Caregivers and to inform recipients of the significant known and potential risks and benefits of emergency use of COVID-19 convalescent plasma. 37, 38  
Healthcare facilities and healthcare providers administering high-titer COVID-19 convalescent plasma must comply with certain mandatory record keeping and reporting requirements (including adverse event reporting). 38 Consult the EUA, 37 EUA fact sheet for healthcare providers, 38 and EUA fact sheet for patients and parents/caregivers 41 for additional information.  
The EUA states that high-titer COVID-19 convalescent plasma should not be considered a new standard of care for the treatment of patients with COVID-19. FDA states that adequate and well-controlled randomized trials remain necessary to determine optimal product...

Open-label, randomized, controlled study in Netherlands (Gharbharan et al; Con-COVID study): Preliminary (non-peer-reviewed) data from a study of 86 hospitalized adults with COVID-19 found no significant difference in mortality, duration of hospital stay, or disease severity on day 15 in patients treated with convalescent plasma (300 mL of convalescent plasma containing anti-SARS-CoV-2 neutralizing antibody titers of ≥1:80 as determined by a SARS-CoV-2 plaque reduction neutralization test) compared with standard of care. **44 Note:** Anti-SARS-CoV-2 antibodies were detected at baseline in 53/66 patients who had been symptomatic for 10 days prior to study enrollment. Neutralizing antibodies were detected in 44/56 (79%) patients tested with median titers comparable to the donors (1:160). These findings raised concerns about the potential benefit of convalescent plasma in the study population and the study was terminated. **44**

Open-label, randomized, controlled study in China (Li et al): Results of this study in 103 adults with severe or life-threatening COVID-19 found no significant difference in time to clinical improvement within 28 days, mortality, or time to hospital discharge in patients treated with convalescent plasma (containing a high titer of antibody to SARS-CoV-2) plus standard of care compared with standard of care alone. **28**

Convalescent plasma therapy was well tolerated by the majority of patients; 2 cases of transfusion-associated adverse events were reported. **23** There was a signal of possible benefit in the subgroup of patients with severe COVID-19 disease. **28, 29** However, the study had several limitations that preclude any definite conclusions, including the possibility of being underpowered as the result of early termination because of the lack of available patients. **28, 29** In addition, most patients received convalescent plasma treatment at least 14 days after symptom onset and it is unclear whether earlier treatment would have resulted in greater benefit. **28, 29**

Open-label, single-arm, phase 2 study (Ibrahim et al): Data from a study of 38 patients with severe COVID-19 found no significant difference in mortality, duration of hospital stay, or disease severity on day 15 in patients treated with convalescent plasma (containing anti-SARS-CoV-2 neutralizing antibody titers of ≥1:80 as determined by a SARS-CoV-2 plaque reduction neutralization test) compared with standard of care. **28** The study had several limitations including the possibility of being underpowered as the result of early termination because of the lack of available patients. **28, 29**

Limited clinical evidence suggests the potential therapeutic window following symptom onset may be longer in patients with suppressed or deficient humoral immunity. **38**

** Available data suggest that serious adverse effects following administration of COVID-19 convalescent plasma are infrequent and consistent with the risks associated with plasma infusions for other indications. Risks associated with COVID-19 convalescent plasma therapy include inadvertent transmission of other infectious agents, allergic reactions, thrombotic complications, transfusion-associated circulatory overload, transfusion-related acute lung injury (TRALI), antibody-dependent enhancement of infection, febrile nonhemolytic reactions, hemolytic reactions, hypothermia, metabolic complications, and post-transfusion purpura. Theoretical risks of COVID-19 convalescent plasma therapy include antibody-dependent enhancement of SARS-CoV-2 infection and long-term immunosuppression. **25**

** May be contraindicated in patients with a history of severe allergic reactions or anaphylaxis to plasma transfusions. **38** The NIH COVID-19 Treatment Guidelines Panel recommends consulting a transfusion medicine specialist for patients with a history of severe allergic or anaphylactic transfusion reactions. **25**

** Pediatric Use: Safety and effectiveness in pediatric patients have not been established; a decision to use high-titer convalescent plasma in patients <18 years of age should be based on an individualized assessment of risks and benefits in consultation with a pediatric infectious disease specialist. **25, 38** The NIH COVID-19 Treatment Guidelines...

**Open-label, randomized, controlled study in India (Agarwal et al; PLACID trial):** Preliminary (non-peer-reviewed) data from a study of 464 moderately ill adults hospitalized with COVID-19 found no significant difference in 28-day mortality or progression to severe disease in patients treated with convalescent plasma (2 transfusions of 200 mL) plus standard of care compared with standard of care alone. Convalescent plasma therapy was well tolerated by the majority of patients; adverse effects included local infusion site reaction, chills, nausea, bradycardia, dizziness, pyrexia, tachycardia, dyspnea, and IV catheter blockage. |

**Open-label, randomized, controlled study in Chile (Balcells et al):** Preliminary (non-peer-reviewed) data from a study of 58 adults hospitalized within 7 days of COVID-19 symptom onset with risk factors for disease progression and without mechanical ventilation found no significant difference in composite outcome of death, mechanical ventilation, or prolonged hospitalization. **Panel states that there are insufficient data to either recommend for or against the use of convalescent plasma for the treatment of COVID-19 in hospitalized children who do not require mechanical ventilation.** The Panel recommends against use of convalescent plasma for the treatment of COVID-19 in mechanically ventilated pediatric patients.  

**Pregnancy:** Safety and effectiveness of convalescent plasma during pregnancy have not been evaluated; however, pathogen-specific immunoglobulins are used clinically during pregnancy to prevent infection from varicella-zoster virus (VZV) and rabies virus. **FDA does not collect COVID-19 convalescent plasma and does not provide such plasma; healthcare providers and acute care facilities obtain convalescent plasma from FDA-registered or licensed blood establishments. [11, 37]** Information on obtaining such plasma may be available at [www.redcrossblood.org](http://www.redcrossblood.org) or [www.aabb.org](http://www.aabb.org). **FDA issued a guidance for industry to provide recommendations to healthcare providers and investigators regarding COVID-19 convalescent plasma, which may be used under the EUA, and investigational COVID-19 convalescent plasma, which does not meet all conditions of the EUA and/or is being used under an investigational new drug application (IND).** This guidance document includes recommendations regarding pathways available for administering or studying COVID-19 convalescent plasma, collection of such plasma (including donor eligibility and qualifications, testing such plasma for anti-SARS-CoV-2 antibodies, product labeling, and recordkeeping). **Additional pathways (outside of the EUA) for administering or studying the use of investigational COVID-19 convalescent plasma:**
admission (≥14 days) in patients who received convalescent plasma (up to two transfusions of 200 mL) immediately following hospital admission compared with those who received convalescent plasma at clinical deterioration. Two patients developed severe respiratory deterioration within 6 hours after transfusion of convalescent plasma and were categorized as possible transfusion-associated acute lung injury (TRALI) type II. 47

Expanded access IND protocol in US (Joyner et al): Analysis of 35,322 adults hospitalized with laboratory-confirmed SARS-CoV-2 infection who had or were considered at high risk of progression to severe or life-threatening COVID-19 who participated in a US FDA Expanded Access Program (NCT04338360) suggests that 7- and 30-day mortality rates are substantially reduced in patients transfused with convalescent plasma within 3 days of COVID-19 diagnosis. Patients received at least one unit (approximately 200 mL) of ABO-compatible COVID-19 convalescent plasma IV according to institutional transfusion guidelines. A statistically significant difference in crude 7-day mortality was observed between patients transfused with convalescent plasma within 3 days of COVID-19 diagnosis compared with those transfused with convalescent plasma 4 or more days after COVID-19 diagnosis (8.7 vs 11.9%). Similar findings were observed for 30-day mortality rate (21.6 vs 26.7%). A reduction in 7- and 30-day mortality rate also was observed in patients transfused with convalescent plasma containing higher IgG antibody levels (>18.45 signal-to-cut-off [S/Co] ratio) compared with those transfused with convalescent plasma containing lower IgG antibody levels ≤18.45 S/Co. 36 Analysis of key safety indicators in 20,000 adults who participated in this Expanded Access Program suggests that IV transfusion of convalescent plasma is safe in hospitalized patients with COVID-19. Within the first 4 hours after transfusion, 146 serious adverse events (i.e., transfusion-associated circulatory overload, transfusion-related acute lung injury [TRALI], severe allergic transfusion reaction) were reported (incidence of <1% of all transfusions with a mortality rate of 0.3%).

1). Clinical Trials: Requests to study use of COVID-19 convalescent plasma should be submitted to FDA under the traditional IND regulatory pathway. 11
2). Intermediate-size Population Expanded Access IND: FDA is accepting requests for expanded access INDs for use of COVID-19 convalescent plasma in patients with serious or immediately life-threatening COVID-19 who are not eligible or are unable to participate in randomized clinical trials. Consult the FDA guidance document for specific information on applying for an expanded access IND for more than a single patient. 11
3). Single Patient Emergency Expanded Access IND (IND): Licensed physicians seeking to administer COVID-19 convalescent plasma to individual patients with serious or life-threatening COVID-19 may request an individual patient expanded access IND from the FDA. Consult the FDA guidance document for specific information on applying for a single patient IND. 11

Donor eligibility: The FDA guidance states that COVID-19 convalescent plasma for use under the EUA or for use under an IND may be collected from individuals who meet the following qualifications: 11

1). Laboratory-confirmed evidence of COVID-19 infection in individuals who had symptoms or laboratory-confirmed evidence from 2 different tests in those who did not have a prior positive diagnostic test and/or never had symptoms of COVID-19. 11
2). Complete resolution of symptoms for at least 14 days before donation (a negative result for COVID-19 by a diagnostic test is not necessary to qualify the donor). 11
3). Male donors, female donors who have never been pregnant, or female donors who have been tested since their most recent pregnancy and results interpreted as negative for HLA antibodies. 11

<td>interval between symptom onset and convalescent plasma donation was 45.1 days; predictors of higher antibody titers in the donors included advanced age, fever, absence of myalgia, fatigue, ABO blood type, and previous hospitalization. In this study, 10 hospitalized adults with severe or life-threatening COVID-19 received 1 or 2 units (approximately 300 mL per unit administered IV over 4 hours) of ABO-compatible COVID-19 convalescent plasma (units had SARS-CoV-2 anti-RBD antibody titers of 1:73 to 1:3892 and anti-spike antibody titers of 1:69 to 1:2921) within 21 days after symptom onset and 80% of these patients had a significant increase in SARS-CoV-2 anti-spike and anti-RBD antibody titer by post-transfusion day 3 and were discharged after clinical improvement; antibody titers in the convalescent plasma recipients were independent of donor antibody titer. SARS-CoV-2 antibody titers in the convalescent plasma recipients continued to increase for up to 14 days in 4 recipients; however, 2 severely ill patients receiving extracorporeal membrane oxygenation (ECMO) who received convalescent plasma on day 20-21 of illness and had SARS-CoV-2 anti-spike antibody titers of up to 1:13,833 on day 0 had a decrease in antibody titer after receiving convalescent plasma. No convalescent plasma recipients experienced toxicity associated with the transfusion or clinical deterioration or worsening of disease status immediately related to plasma transfusion. Convalescent plasma transfusion was safe in high-risk individuals in this study (i.e., immunosuppressed, end-stage renal disease).</td>

<tr>
<td>Famotidine</td>
<td>Updated 4/30/21</td>
<td>56:28.12 Histamine H₂ Antagonists</td>
<td>Currently no known published prospective clinical trial evidence supporting efficacy or safety for treatment of COVID-19. <strong>Randomized, double-blind, placebo-controlled, comparative trial</strong> (NCT04370262) is evaluating high-dose IV famotidine plus standard care vs placebo plus standard care in hospitalized adults with moderate to severe COVID-19; targeted enrollment is at least 942 patients. <strong>Other randomized clinical trials evaluating famotidine for treatment of COVID-19 may be registered at clinicaltrials.gov.</strong></td>
<td>Dosage in NCT04370262: Famotidine is being given IV in 120-mg doses (proposed total daily dosage of 360 mg) for maximum of 14 days or until hospital discharge, whichever comes first. Proposed daily dosage in NCT04370262 is 9 times the usual manufacturer-recommended IV adult dosage; the study excludes patients with creatinine clearance (Cl$<em>{cr}$) ≤ 50 mL/minute, including dialysis patients; renally impaired patients may be at increased risk of adverse CNS effects since drug half-life is closely related to Cl$</em>{cr}$.</td>
<td>Safety and efficacy for treatment of COVID-19 not established. IDSA suggests against using famotidine for the sole purpose of treating COVID-19 in hospitalized patients with severe COVID-19 outside of the context of a clinical trial.</td>
</tr>
</tbody>
</table>

In vitro data suggest famotidine does not bind to SARS-CoV-2 proteases, although antiviral activity was not tested in cell lines that express H₂ receptors. **No in vitro antiviral activity against SARS-CoV-2 observed in infected Vero E6 cells.** A possible role for dysfunctional mast cell activation and histamine release in mediating clinical manifestations of COVID-19 has been postulated; it is further postulated that the principal action of famotidine in COVID-19 may relate to activity at H₂ receptors. **Anecdotal observations:**

Observations based on retrospective medical record review indicated that many Chinese COVID-19 survivors had received famotidine for chronic heartburn; mortality rate appeared to be lower in hospitalized COVID-19 patients receiving famotidine than in patients not receiving the drug.

|         |            |           | admission. Multivariable logistic regression analysis showed **no significant association between severe COVID-19 disease and use of famotidine or PPIs**.  
  **Retrospective, matched, multiple-hospital study** investigating the association between in-hospital famotidine use (within 24 hours of admission) and mortality in patients with confirmed COVID-19: Famotidine users and nonusers were matched by age, gender, race and ethnicity, body mass index, comorbidities, and in-hospital hydroxychloroquine use. Patients who died or required intubation within 48 hours of admission were excluded. The post-match cohort included 410 patients (35.5%) who received famotidine and 746 matched controls (64.5%). Multivariable logistic regression analysis within the matched cohort showed **no association between in-hospital famotidine use and 30-day mortality** after adjustment for WHO severity rating, smoking status, and use of antiviral and supportive therapies.  
  **Retrospective, multihospital, cohort study** in hospitalized patients with an electronic health record (EHR) diagnosis of COVID-19: **Famotidine use did not reduce mortality or the combined end point of death plus intensive intervention** (mechanical ventilation, tracheostomy, or extracorporeal membrane oxygenation [ECMO]) at 30 days after admission compared with nonuse of famotidine or compared with use of proton-pump inhibitors (PPIs) or hydroxychloroquine. Medication use was determined from dispensing records on the day of admission; famotidine nonuse was defined as no history of exposure to the drug on or before the day of admission. Patients receiving intensive services on or within 30 days prior to admission were excluded. The study included 1816 famotidine users, 2193 PPI users, 5950 hydroxychloroquine users, and 26,820 nonusers of famotidine. Most famotidine users received the drug orally (64%) at a low dose of 20 mg (73%) on the day of admission. After propensity score stratification, the hazard ratio for death was 1.03, 1.14, or 1.03 for famotidine use vs. |
no famotidine use, vs. PPI use, or vs. hydroxychloroquine use, respectively. Results for the combined end point were similar.  

**Meta-analysis** of the above 5 retrospective studies, which included a total of 36,635 patients, found no significant protective effect for famotidine in reducing the risk of progression to severe illness, death, or intubation in patients with COVID-19 (odds ratio = 0.82 [95% CI = 0.52-1.3]).

Uncontrolled series of hospitalized patients with COVID-19 receiving open-label, combined H2 and H3 antagonist therapy (famotidine and cetirizine) for ≥48 hours: Total of 110 patients at a single hospital received famotidine 20 mg and cetirizine hydrochloride 10 mg orally or IV every 12 hours; concomitant therapy included hydroxychloroquine (85%), tocilizumab (51%), methylprednisolone (31%), and convalescent plasma (30%). Findings included a 16.4% overall rate of intubation, 7.3% rate of intubation after 248 hours of treatment, 15.5% mortality rate, and 11-day average hospital stay. **Note:** Comparisons were limited to published outcome data from other locales for patients receiving “standard-of-care” regimens.

Fluvoxamine dosage in the open-label cohort was initial dose of 50 mg once daily then 100 mg twice daily for approximately 15 days; dosage can be adjusted based on tolerability. **NIH COVID-19 Treatment Guidelines Panel states that there are insufficient data to recommend either for or against use of fluvoxamine for the treatment of COVID-19. The panel states that results from adequately powered, well-designed, and well-conducted clinical trials are needed to provide more specific, evidence-based guidance on the role of fluvoxamine in the treatment of COVID-19.**

Some potential advantages of fluvoxamine include that it’s a relatively safe, inexpensive, and available drug that can be given orally. Unlike some selective serotonin-reuptake inhibitors, fluvoxamine is not associated with QT-interval prolongation. In addition, it has been widely used in children and adults and may help treat depressive and anxiety symptoms that may occur in patients with COVID-19. However, fluvoxamine...

<td></td>
<td></td>
<td>Further studies needed to establish whether the anti-inflammatory effects of fluvoxamine observed in nonclinical studies also occur in humans and are clinically relevant in the COVID-19 setting. &lt;sup&gt;5&lt;/sup&gt; patients in the fluvoxamine group and in 6 of 72 patients (8.3%) in the placebo group. This preliminary study had several limitations, including a relatively small sample size, a single geographic area, a limited number of events occurred, and a short follow-up period. In addition, ascertaining clinical deterioration of patients was difficult because all assessments were made remotely. &lt;sup&gt;3, 6&lt;/sup&gt; A larger, fully remote, randomized, placebo-controlled, phase 3 trial (the StopCovidTrial) evaluating fluvoxamine in adults with COVID-19 (expected enrollment 880) is currently under way by the same group of investigators as the Lenze et al study above (NCT04668950). &lt;sup&gt;3&lt;/sup&gt; Seftel and Boulware reported on a prospective open-label cohort of patients in whom fluvoxamine was given during a mass COVID-19 outbreak at a horse racing track in California. A total of 65 patients with laboratory-confirmed COVID-19 chose to receive fluvoxamine (loading dose of 50-100 mg, then 50 mg twice daily for 14 days) and 48 patients declined the drug and received observation only. Hospitalization occurred in 0% of the fluvoxamine-treated patients compared with 12.5% of those receiving observation alone (2 of these patients required ICU treatment with mechanical ventilation and one of these patients died). At 14 days, residual symptoms persisted in none of the fluvoxamine-treated patients compared with 60% of those receiving observation alone. No serious adverse events were reported in the patients taking fluvoxamine. Limitations of this study include that it was a nonrandomized trial with a small sample size and limited data were collected during the course of the study. &lt;sup&gt;3, 6&lt;/sup&gt; Other clinical trials evaluating use of fluvoxamine in patients with COVID-19 may be registered at clinicaltrials.gov. &lt;sup&gt;4&lt;/sup&gt; may cause clinically important drug interactions because it is a potent inhibitor of CYP isoenzymes 1A2 and 2C19 and a moderate inhibitor of CYP isoenzymes 2C9, 2D6, and 3A4. &lt;sup&gt;1, 3, 5, 6&lt;/sup&gt; Pediatric use: No data available to date on use of fluvoxamine for prevention or treatment of COVID-19 in pediatric patients. &lt;sup&gt;6&lt;/sup&gt;</td>

**Retrospective cohort studies:**
In a study of 13,981 pts in China hospitalized with COVID-19, statin use during hospitalization was associated with lower risk of mortality. The 28-day all-cause mortality was 22% lower in pts who received statins during hospitalization compared with pts who did not receive statins. Among propensity-score-matched pts (861 pts in the statin group vs 3444 matched pts in the non-statin group), the risk of 28-day all-cause mortality was 42% lower in pts who received statins during hospitalization compared with those who did not receive statins. In addition, lower incidence of invasive mechanical ventilation was observed in the statin-treated pts. The authors note that pts in the statin group were older and had a higher prevalence of comorbidities and more severe symptoms at baseline; matched non-statin pts therefore had more severe baseline symptoms and comorbidities than unmatched pts, which could account for the increased mortality in the non-statin group after propensity score matching. \(^11\)

In a national registry-based cohort study in Denmark, statin use was not associated with decreased risk of all-cause mortality or severe disease in patients with COVID-19. This study captured data from 4842 pts with a hospital encounter (e.g., inpatient, outpatient, ED visit) and COVID-19; 17.4% were receiving statin therapy (defined as individuals having filled a prescription for a statin within 6 months prior to COVID-19 diagnosis). After adjusting for baseline characteristics, including comorbidities (e.g., history of ischemic heart disease, stroke, diabetes mellitus, hypertension, malignancy, chronic kidney disease, liver disease) and concomitant medications, **Pts with cardiovascular disease are at an increased risk of serious COVID-19 infections.** \(^3\)

In pts with active COVID-19 who may develop severe rhabdomyolysis, it may be advisable to withhold statin therapy for a short period of time. \(^3\)

Most statins are substrates for the CYP450 system; potential for drug interactions. \(^7\)

Clinicians should ensure that their high-risk primary prevention (for ASCVD) pts are on guideline-directed statin therapy. \(^3\)
there was no difference between statin and non-statin pts in the 30-day risk of all-cause mortality, severe disease, and a composite of both outcomes. The study also found no differences in these outcomes among statin pts when stratified by specific statin or statin intensity.\textsuperscript{23}

In a study of 2157 pts hospitalized with COVID-19 at multiple centers in Spain (NCT04407273; STACOV), statin use prior to hospitalization was associated with a lower in-hospital mortality rate compared with no statin use (19.8 vs 25.4%), particularly in pts who continued statin therapy during hospitalization (17.4%). Approximately 58% of the 581 pts receiving statins prior to hospitalization continued therapy at the same dosage during hospitalization. In this study, propensity matching failed to achieve similar baseline characteristics between statin and non-statin pts; pts were therefore matched using a genetic matching method.\textsuperscript{20}

A study of 2147 pts hospitalized with COVID-19 at 2 hospitals in China found an association between statin use and lower mortality and improved clinical outcomes compared with no statin use. In this study, 11.6% of patients were receiving statin therapy prior to admission that was continued during hospitalization. After propensity score matching, statin use was associated with a lower risk of death, ARDS, and ICU admission compared with no statin use (adjusted hazard ratios: 0.251, 0.232, and 0.381, respectively).\textsuperscript{24}

In a study of 842 pts hospitalized with COVID-19 at multiple centers in Italy, statin use was not associated with a difference in in-hospital mortality compared with no statin use. In this study, 21% of pts were receiving statin therapy prior to admission. After propensity score matching, although pts receiving statin therapy presented with worse disease severity (as assessed by the National Early Warning Score [NEWS]) and worse radiological features compared with non-statin pts, there was no difference in in-hospital mortality between statin and non-statin pts. The study also found that,
<table>
<thead>
<tr>
<th>Drug(s)</th>

<th>Rationale</th>
<th>Trials or Clinical Experience</th>
<th>Dosage*</th>
<th>Comments</th>
</tr>
</thead>
</table>
|         |            |           | although pts receiving high- or moderate-intensity statin therapy had worse clinical presentation of disease compared with those receiving low-intensity statin therapy, in-hospital mortality was similar between the groups.  
In a study of 170 pts hospitalized for COVID-19 at a single US center, statin use prior to admission was associated with reduced risk of developing severe disease and, among those without severe disease, faster time to recovery. In this study, 27% of pts reported using statins within 30 days prior to hospitalization for COVID-19. Statin use was associated with a 71% lower risk of severe outcome (i.e., death or ICU admission). In addition, rate of recovery in pts without severe disease was higher (hazard ratio for recovery: 2.69) and median time to recovery was shorter for those who received statins. The beneficial effect of statin use on reduction of severe outcomes in pts with COVID-19 was greater than that observed in a large control cohort of COVID-19-negative pts.  
In a study of 249 pts hospitalized with COVID-19 at multiple US centers, statin use prior to hospitalization was associated with lower risk of invasive mechanical ventilation in some models, but there was no substantial association between statin use and in-hospital death or ICU admission.  
In a cohort analysis of 541 pts hospitalized with COVID-19 at a single center in Italy, the association between statin use prior to hospitalization and reduced mortality or disease severity was not statistically significant.  
Statin use was associated with a small, but statistically significant, decrease in mortality compared with no statin use in a multi-center US-based study comparing 2297 COVID-19 pts receiving statins (defined as pts with a medication order for a statin within 10 days before and 7 days after positive SARS-CoV-2 test) with 4594 propensity score-matched non-statinate pts. In this study, the mortality rate was 16.1% in statin users and ranged from 18-20.6%, depending on... |
propensity score iteration, in non-statin users. \(^{30}\)

In a study using the Korean National Health Insurance Service database, prior statin use was associated with a lower risk of mortality in hospitalized COVID-19 pts. This study included 10,448 pts hospitalized for COVID-19 (5.1% were statin users based on prescription records). After propensity score matching, the risk of mortality was 36% lower in statin users compared with non-statin users. \(^{29}\)

**Intensive care pts:** In a study of 87 pts admitted to the ICU with COVID-19 at a single US center, treatment with atorvastatin (40 mg daily) was associated with a reduced risk of death (adjusted hazard ratio: 0.38). \(^{13}\)

**Non-hospitalized pts:** In a study of 154 nursing home residents in Belgium with clinically suspected COVID-19 and/or positive PCR test for SARS-CoV-2, statin use was associated with absence of symptoms (i.e., asymptomatic infection) in this cohort; 45% of the 31 pts receiving statin therapy remained asymptomatic compared with 22% of the 123 pts not receiving statins. \(^{10}\)

In a retrospective cohort study in Korea, statin use was associated with lower odds of developing COVID-19 compared with no statin use. This study included 122,040 individuals without COVID-19 in the National Health Insurance Service database in Korea (18.5% were statin users based on prescription records). The primary endpoint was COVID-19 diagnosis. After propensity score matching, the odds of developing COVID-19 were 35% lower in statin users compared with non-statin users. However, among the 7780 pts diagnosed with COVID-19, there was no substantial difference in hospital mortality between statin users and those not receiving statins. \(^{28}\)

**Meta-analyses:** Preliminary findings from a meta-analysis (Kow & Hasan) of 4 cohort or case-control studies which included a total of 8990 pts with COVID-19 suggest that statin use is

</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>associated with a 30% reduction in risk of severe or fatal outcome in pts with COVID-19.(^ {14}) However, another meta-analysis of 9 cohort or case-control studies (Hariyanto &amp; Kurniawan) did not find an association between statin use and improved severity or mortality outcomes in pts with COVID-19. This meta-analysis included a total of 3449 pts with COVID-19 and included 2 of the same studies used in the Kow &amp; Hasan analysis.(^ {15}) A larger meta-analysis of observational studies (Scheen) found that statin use was not associated with reduced in-hospital mortality (13 studies with a total of 42,722 pts) or disease severity (11 studies with a total of 14,022 pts). In studies using multivariate analyses or adjusting for covariates, statin use was associated with lower rates of in-hospital mortality and reduced disease severity (adjusted odds ratio: 0.73). In addition, studies that utilized propensity-score matching for comparison found a statistically significant lower risk of in-hospital mortality in statin users compared with those not receiving statins (hazard ratios ranging from 0.48 to 0.88). The authors note that there was considerable heterogeneity between studies.(^ {22}) Another meta-analysis (Pal et al.), which included 14 observational studies with a total of 19,988 pts, found that although analysis of unadjusted data indicated current and/or in-hospital statin use was not associated with differences in clinical outcomes (e.g., mortality, ICU admission), when analysis was limited to the 5 studies that reported adjusted odds and/or hazard ratios, statin use was associated with a 36-49% reduced risk of adverse clinical outcomes.(^ {26}) Another meta-analysis (Permana et al.; 13 observational studies with a total of 52,122 pts) investigated whether in-hospital use of statins had an effect on mortality in patients with COVID-19. In 8 studies that specifically reported the use of statins during hospitalization, in-hospital statin use was associated with a 46% lower risk of mortality compared with no statin use.</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\(^a\)
In the remaining 5 studies where statin use was discontinued or not explicitly stated as being continued during hospitalization, no difference in mortality was observed between pre-hospitalization statin use and no prior statin use. 17

In pts with diabetes mellitus hospitalized with COVID-19, observational studies have also yielded conflicting results with regards to statin use. 17, 18, 19 In a US single-center observational study, among 2266 pts with diabetes mellitus hospitalized with COVID-19, statin use during hospitalization was associated with reduced in-hospital mortality (hazard ratio 0.51). 19 In addition, a large registry-based cohort study in England found an association between statin use (i.e., having a prescription for statins) and reduced COVID-19-related mortality in pts with type 2 diabetes mellitus. 17 However, a cohort study of 2449 pts with type 2 diabetes mellitus hospitalized with COVID-19 at multiple centers in France (CORONADO study) found that statin use prior to hospitalization was associated with higher 7- and 28-day mortality compared with no statin use (odds ratio 1.74 and 1.46, respectively). 18

Other respiratory conditions:
Preliminary findings have shown mixed results with other respiratory illnesses; some observational studies suggest statin therapy is associated with a reduction in various cardiovascular outcomes and possibly mortality in pts hospitalized with influenza and/or pneumonia. 3-6

Other clinical trials evaluating use of statins in pts with COVID-19 may be registered at clinicaltrials.gov. 3

**COMMERCIAL AVAILABLE IMMUNE GLOBULIN (NON-SARS-COV-2-SPECIFIC IGIV)**

**SARS Experience:** IGIV has been used in the treatment of SARS. Benefits were unclear because of patient comorbidities, differences in stage of illness, and effect of other treatments; IGIV may have contributed to hypercoagulable state and thrombotic complications in some patients.

**Open-label, prospective, randomized, controlled study in the US (Sakoulas et al; NCT04411667):** Preliminary (non-peer-reviewed) data from a study of 33 adults with COVID-19 and moderate to severe hypoxia (defined as SpO₂ ≤ 96% requiring ≥ 4 liters O₂ by nasal cannula) but not on mechanical ventilation found that IGIV significantly improved hypoxia and reduced hospital length of stay and progression to mechanical ventilation in patients with alveolar-arterial (A-a) gradient ≤ 200 mm Hg treated with IGIV (Octagam® 10% 0.5 g/kg daily for 3 days) plus standard of care compared with standard of care alone. All 16 patients in the IGIV group received premedication with methylprednisolone (40 mg IV) prior to each IGIV dose and 5 of these received additional glucocorticoid therapy; 10/17 patients in the standard of care group received some glucocorticoid therapy.

**COVID-19 case reports in China (Cao et al):** Treatment with IGIV at the early stage of clinical deterioration was reported to provide some clinical benefit in 3 adults with severe COVID-19; 2 patients also received antivirals and 1 patient also received short-term steroid treatment. Patients were afebrile within 1-2 days and breathing difficulties gradually improved within 3-5 days of IGIV administration.

<td></td>
<td>In vitro evidence of activity against SARS-CoV-2 in infected Vero-hSLAM cells reported with high concentrations of the drug&lt;sup&gt;1&lt;/sup&gt;</td>
<td>Pilot observational study comparing efficacy of add-on ivermectin in pts with mild to moderate COVID-19 (not peer reviewed): A total of 16 pts received a single dose of oral ivermectin (0.2 mg/kg) given on the day of hospital admission in addition to initiation of treatment with hydroxychloroquine and azithromycin, and results were compared with 71 pts who received hydroxychloroquine and azithromycin alone (matched controls). The primary outcome was percentage of pts cured (defined as symptoms free to be discharged from the hospital and 2 consecutive negative PCR tests from nasopharyngeal swabs at least 24 hours apart) within 23 days. The investigators reported that all 16 pts who received ivermectin were cured compared with 97% of pts who did not receive ivermectin and the mean duration of hospitalization was shorter in the ivermectin group (7.6 days) than in the control group (13.2 days). Note: These results need to be validated in a larger prospective trial.</td>
<td></td>

</table>

**NIH panel recommends against** use of ivermectin for preexposure prophylaxis (PrEP) or postexposure prophylaxis (PEP) for prevention of SARS-CoV-2 infection, except in a clinical trial. Only limited clinical trial data are available to date regarding use of ivermectin for PrEP or PEP. Although some potentially promising results were reported in a few initial studies (some not peer reviewed), these findings are limited by design of the studies, small sample sizes, and lack of details regarding safety and efficacy of the drug.

**IDSA suggests against** use of ivermectin for treatment of severe COVID-19 in hospitalized patients and use of ivermectin for treatment of COVID-19 in outpatients outside of the context of a clinical trial. Manufacturer (Merck) states that, to date, there is no scientific basis from preclinical studies for a potential therapeutic effect of ivermectin against COVID-19, no meaningful evidence of clinical activity or clinical efficacy of the drug in patients with COVID-19, and a concerning lack of safety data in the majority of studies. In addition, available data do not support the safety and efficacy of ivermectin beyond the doses...

</thead>
</table>
| | | | subgroup of pts with severe pulmonary involvement also indicated lower mortality in the ivermectin group (38.8 vs 80.7%). There was no difference in duration of hospitalization between the groups in either the unmatched or matched cohorts (median of 7 days for both groups). There also was no significant difference in extubation rates between groups in either the unmatched or matched cohorts. **Note:** The effect of ivermectin on viral load was not evaluated and the impact of confounding factors in these patients (e.g., time from diagnosis to initiation of treatment, differences in drugs used for standard care and variances in clinical benefits of such drugs) is not known.  

**Randomized, double-blind, placebo-controlled trial in hospitalized adults (Ahmed et al):** A total of 72 adults with COVID-19 were randomized to receive ivermectin (12 mg orally once daily for 5 days), ivermectin (single 12-mg oral dose) with doxycycline (200 mg orally on day 1, then 100 mg every 12 hours for 4 days), or placebo. The primary end points were time required for virologic clearance (i.e., negative RT-PCR on nasopharyngeal swab) and remission of fever and cough within 7 days. The mean time to viral clearance was 9.7 days in the 5-day ivermectin group, 11.5 days in the ivermectin with doxycycline group, and 12.7 days in the placebo group. There was no significant difference between groups in remission of fever and cough.  

**Randomized, double-blind, placebo-controlled trial in adults with mild COVID-19 (López-Medina et al; NCT04405843):** A total of 476 adults (hospitalized or outpatients) with mild disease and symptom onset within the previous 7 days were randomized 1:1 to receive a 5-day regimen of ivermectin (300 mcg/kg daily as an oral solution) or placebo. The primary outcome was the time from randomization to complete resolution of symptoms within the 21-day follow-up. The primary efficacy analysis population included 398 pts (200 received ivermectin and 198 received placebo). Baseline demographic and disease and populations indicated in regulatory agency-approved prescribing information.  

Ivermectin plasma concentrations attained with dosages recommended for treatment of parasitic infections are substantially lower than concentrations associated with in vitro inhibition of SARS-CoV-2; pharmacokinetic modeling predicts that plasma concentrations attained with dosages up to 10 times higher than usual dosage also are substantially lower than concentrations associated with in vitro inhibition of the virus.  

FDA issued a warning concerning possible inappropriate use of ivermectin products intended for animals as an attempt to self-medicate for the treatment of COVID-19. |

Updated 2/11/21

**Potential harm:** Concern that use of nebulized drugs (e.g., albuterol) for the management of respiratory conditions in patients with COVID-19 infection may distribute the virus into the air and expose close contacts. American College of Allergy, Asthma & Immunology (ACAAI) recommends that nebulized albuterol should be administered in a location that minimizes exposure to close contacts who do not have COVID-19 infection. In the home, choose a location where air is not recirculated (e.g., porch, patio, or garage) or areas where surfaces can be cleaned easily or may not need cleaning. In hospitals, clinicians typically use nebulizers to deliver medications such as albuterol, but are being encouraged to switch to use of metered-dose or dry powder inhalers in patients who are awake and who can perform specific breathing techniques because of the risk of the virus becoming airborne when treating patients infected with COVID-19.

<td>Nonsteroidal Anti-inflammatory Agents (NSAIAs)</td>
<td>28:08.04</td>
<td>Ibuprofen: Speculative link between ibuprofen and increased ACE2 expression, which possibly could lead to worse outcomes in COVID-19 patients 1</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Updated 4/30/21</strong></td>
<td></td>
<td>In a national registry-based cohort study in Denmark, NSAIA use was not associated with increased 30-day mortality, hospitalization, ICU admission, mechanical ventilation, or renal replacement therapy in individuals who tested positive for SARS-CoV-2. In this study, of the 9236 individuals who had a positive PCR test for SARS-CoV-2, 2.7% had used NSAIA (defined as individuals having filled a prescription for an NSAIA within 30 days prior to a positive SARS-CoV-2 test) based on national community pharmacy records. The authors note that in Denmark, NSAIA are available only by prescription with the exception of low-dose ibuprofen (200 mg) sold over the counter (OTC) in packages of no more than 20 tablets, and such OTC purchases of ibuprofen constituted 15% of total ibuprofen sales and a smaller proportion of total NSAIA sales. This definition of NSAIA use was a major limitation of the study. 14</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>NSAIA use was not associated with increased incidence of COVID-19 (suspected or confirmed) or all-cause mortality in a UK database-based study comparing 13,202 pts with osteoarthritis who were prescribed NSAIA with 12,457 propensity-matched pts who were prescribed comparator analgesics (acetaminophen and codeine/dihydrocodeine). 16</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
|                                              |            | In addition, 2 other large UK database-based cohort studies did not find an association between NSAIA use and increased risk of COVID-19-related death in the general population or in pts with rheumatoid arthritis or osteoarthritis. These studies defined current NSAIA users as individuals with a prescription for an NSAIA within 4 months prior to study entry and compared 536,423 current NSAIA users with 536,423 study entrants.  

Concerns that anti-inflammatory drugs such as ibuprofen may worsen COVID-19 circulated widely in the early months of the pandemic. 5, 12, 14 These reports were based largely on a letter published in *The Lancet Respir Med* stating that increased expression of ACE2 could facilitate infection with COVID-19 and that ibuprofen can increase ACE2. 1, 2 In addition, there were unconfirmed reports of younger, healthy patients who had used ibuprofen to treat early symptoms of COVID-19 and later experienced severe outcomes. 10, 12, 14  |
<p>|                                              |            | A statement attributed to the WHO recommending paracetamol and avoiding ibuprofen as a self-medication was widely circulated in the media; however, such a position by the WHO has not been substantiated. WHO subsequently performed a rapid review of the literature and concluded that there was no evidence at that time of severe adverse events or effects on acute health care utilization, long-term survival, or quality of life in patients with COVID-19 as a result of the use of NSAIA. 9  |
|                                              |            | FDA has stated that it is not aware of scientific evidence connecting the use of NSAIA, such as ibuprofen, with worsening COVID-19 symptoms and will communicate publicly when more information is available. FDA also noted that all prescription NSAIA labels warn that ibuprofen can increase ACE2. 1, 2 Although there currently is no compelling evidence to support an association between ibuprofen and negative outcomes in patients with COVID-19, some experts have recommended preferentially using acetaminophen for treatment of fever 1, 3, 4, 10  |</p>

<td></td>
<td>A consistent finding in patients with severe COVID-19 is a hypercoagulable state, which has been shown to contribute to poor outcomes (e.g., progressive respiratory failure, acute respiratory distress syndrome [ARDS], death). 1, 3, 5, 9, 14, 16, 18, 19 Coagulation abnormalities observed include prothrombotic disseminated intravascular coagulation (DIC), elevated D-dimer levels, high fibrinogen levels, and microvascular and macrovascular thrombosis. 1, 2, 5-10, 13, 14, 16 A consistent finding in patients with ARDS (regardless of the cause) is fibrin deposition and microthrombi formation in the alveoli and pulmonary vasculature. 1, 12, 14</td>
<td>Results of a small phase 1 study suggested possible benefit of plasminogen activators in the treatment of ARDS. 1, 3, 5 In this study, 20 patients with ARDS secondary to trauma and/or sepsis who failed to respond to standard ventilator therapy and were not expected to survive were treated with urokinase or streptokinase; such therapy improved PaO₂ and also appeared to improve survival. 1, 3 There is some evidence suggesting that t-PA (alteplase) may decrease dead-space ventilation in patients with COVID-19-associated ARDS, but whether this leads to improved clinical outcomes is not known. 27, 28 Various case reports or case series describing the use of t-PA in severe COVID-19 patients have been published. 20, 21, 24, 28-30, 31 In one case series of 5 COVID-19 patients who had severe hypoxemia, declining respiratory status, and increasing oxygen requirements, administration of t-PA (alteplase) at an initial IV bolus dose of 25 mg over 2 hours followed by a continuous infusion was associated with survival. 27, 28</td>
<td>t-PA (alteplase): Various IV dosage regimens of t-PA (alteplase) are being evaluated in patients with COVID-19; the optimum dose, route of administration, and duration of treatment remain to be determined. 2, 9, 12, 14, 20 Tenecteplase: A low-dose IV bolus of tenecteplase (0.25 mg/kg or 0.5 mg/kg) is being evaluated in the registered NCT04505592 trial. 12</td>
<td>** NIH COVID-19 Treatment Guidelines Panel states that patients who are receiving NSAIs for an underlying medical condition should not discontinue such therapy unless discontinuation is otherwise warranted by their clinical condition; the panel also states that antipyretic strategy (e.g., use of acetaminophen or NSAIs) in patients with COVID-19 should remain similar to the approaches used in other patients. 5 The Surviving Sepsis Campaign COVID-19 guidelines state that, for critically ill adults with COVID-19 who develop fever, use of acetaminophen over no treatment for fever control is suggested (weak recommendation). 5 IDSA makes no specific recommendation for or against the use of NSAIs in patients with COVID-19. 12 Indomethacin: Additional data needed to determine whether in vitro activity against SARS-CoV-2 correlates with clinical efficacy in the treatment of COVID-19</td>

**Drug(s)** | **AHFS Class** | **Rationale** | **Trials or Clinical Experience** | **Dosage** | **Comments**
---|---|---|---|---|---
IV infusion of 25 mg over the next 22 hours appeared to improve oxygen requirements in all patients and prevent progression to mechanical ventilation in 3 of the patients.  
In another case series, t-PA (doses varied) was administered concomitantly with heparin anticoagulation in 5 critically ill mechanically ventilated COVID-19 patients with apparent thrombotic coagulopathy and ARDS. Although respiratory status in all 5 patients improved following t-PA administration, sustained improvement was observed in only 3 of the patients.  
Other case reports or case series have described the use of t-PA in COVID-19 patients with severe respiratory failure or ARDS who were rapidly deteriorating and were either already on mechanical ventilation or likely to require intubation. Following IV infusion of t-PA (dosages varied), the majority of patients responded with rapid improvement in oxygenation.

Several randomized controlled studies (NCT04357730, NCT04640194) evaluating IV alteplase in patients with ARDS due to COVID-19 are registered at clinicaltrials.gov.

An open-label, nonrandomized pilot study (NCT04356833) is being conducted to evaluate an inhaled formulation of t-PA (via nebulization) in patients with ARDS due to COVID-19; the inhaled formulation of t-PA is investigational at this time.

Several randomized, double-blind, placebo-controlled trials evaluating low-dose IV bolus tenecteplase in conjunction with anticoagulation for the treatment of COVID-19-associated respiratory failure are registered at clinicaltrials.gov.
